FOREWORD

The first broadly recognized national standard for the design and construction of bridges in the United States was published in 1931 by the American Association of State Highway Officials (AASHO), the predecessor to AASHTO. With the advent of the automobile and the establishment of highway departments in all of the U.S. states dating back to just before the turn of the 20th century, the design, construction, and maintenance of most U.S. bridges was the responsibility of these departments and, more specifically, the chief bridge engineer within each department. It was natural, therefore, that these engineers, acting collectively as the AASHTO Highway Subcommittee on Bridges and Structures (now the Committee on Bridges and Structures), would become the author and guardian of this first bridge standard.

This first publication was entitled *Standard Specifications for Highway Bridges and Incidental Structures*. It quickly became the *de facto* national standard and, as such, was adopted and used by not only the state highway departments but also other bridge-owning authorities and agencies in the United States and abroad. Rather early on, the last three words of the original title were dropped and it has been reissued in consecutive editions at approximately four-year intervals ever since as *Standard Specifications for Highway Bridges*, with the final 17th edition appearing in 2002.

The body of knowledge related to the design of highway bridges has grown enormously since 1931 and continues to do so. Theory and practice have evolved greatly, reflecting advances through research in understanding the properties of materials, in improved materials, in more rational and accurate analysis of structural behavior, in the advent of computers and rapidly advancing computer technology, in the study of external events representing particular hazards to bridges such as seismic events and stream scour, and in many other areas. The pace of advances in these areas has, if anything, stepped up in recent years.

In 1986, the Subcommittee submitted a request to the AASHTO Standing Committee on Research to undertake an assessment of U.S. bridge design specifications, to review foreign design specifications and codes, to consider design philosophies alternative to those underlying the Standard Specifications, and to render recommendations based on these investigations. This work was accomplished under the National Cooperative Highway Research Program (NCHRP), an applied research program directed by the AASHTO Standing Committee on Research and administered on behalf of AASHTO by the Transportation Research Board (TRB). The work was completed in 1987, and, as might be expected with a standard incrementally adjusted over the years, the Standard Specifications were judged to include discernible gaps, inconsistencies, and even some conflicts. Beyond this, the specification did not reflect or incorporate the most recently developing design philosophy, load-and-resistance factor design (LRFD), a philosophy which had been gaining ground in other areas of structural engineering and in other parts of the world such as Canada and Europe.

From its inception until the early 1970s, the sole design philosophy embedded within the Standard Specifications was one known as working stress design (WSD). WSD establishes allowable stresses as a fraction or percentage of a given material's load-carrying capacity, and requires that calculated design stresses not exceed those allowable stresses. Beginning in the early 1970s, WSD began to be adjusted to reflect the variable predictability of certain load types, such as vehicular loads and wind forces, through adjusting design factors, a design philosophy referred to as load factor design (LFD).

A further philosophical extension results from considering the variability in the properties of structural elements, in similar fashion to load variabilities. While considered to a limited extent in LFD, the design philosophy of LRFD takes variability in the behavior of structural elements into account in an explicit manner. LRFD relies on extensive use of statistical methods, but sets forth the results in a manner readily usable by bridge designers and analysts.

Starting with the Eighth Edition of the AASHTO *LRFD Bridge Design Specifications*, interim changes to the Specifications were discontinued, and new editions are published on a three-year cycle. Changes are balloted and approved by at least two-thirds of the members of the Committee on Bridges and Structures. AASHTO members include the 50 State Highway or Transportation Departments, the District of Columbia, and Puerto Rico. Each member has one vote. The U.S. Department of Transportation is a non-voting member.

Orders for specifications may be placed by visiting the AASHTO Store, <https://store.transportation.org>; calling the AASHTO Publication Sales Office toll free (within the U.S. and Canada), 1-800-231-3475; or mailing to P.O. Box 933538, Atlanta, GA 31193-3538. A free copy of the current publication catalog can be downloaded from our website or requested from the Publications Sales Office.

For additional publications prepared and published by the Committee on Bridges and Structures and by other AASHTO Committees, please look online in the AASHTO Store (<https://store.transportation.org>) under “Bridges and Structures.”

Suggestions for the improvement of the *AASHTO LRFD Bridge Design Specifications* are welcomed, just as they were for the *Standard Specifications for Highway Bridges* before them, at www.transportation.org.

The following have served as chair of the Committee on Bridges and Structures since its inception in 1921: E. F. Kelley, who pioneered the work of the Committee; Albin L. Gemeny; R. B. McMinn; Raymond Archiband; G. S. Paxson; E. M. Johnson; Ward Goodman; Charles Matlock; Joseph S. Jones; Sidney Poleynard; Jack Freidenrich; Henry W. Derthick; Robert C. Cassano; Clellon Loveall; James E. Siebels; David Pope; Tom Lulay; Malcolm T. Kerley; Gregg Fredrick; and Carmen Swanwick. The Committee expresses its sincere appreciation of the work of these individuals and of those active members of the past, whose names, because of retirement, are no longer on the roll.

The Committee and AASHTO staff would also like to thank the late Diane Long (1964–2023) of Modjeski and Masters for her many years of dedicated service in helping prepare previous editions of these Specifications, as well as her help on the current edition. Her aid has been sorely missed during the production of this edition of the *LRFD Bridge Design Specifications*, and our thoughts are with her friends, family, and colleagues.

The *AASHTO LRFD Bridge Design Specifications*, Tenth Edition contains the following 15 Sections and an index:

- Detailed Tables of Contents precede each section. The last article of each section is a list of references displayed alphabetically by author.

Please note that the AASHTO materials standards (starting with M or T) cited throughout the *LRFD Bridge Design Specifications* can be found in *Standard Specifications for Transportation Materials and Methods of Sampling and Testing*, adopted by the AASHTO Committee on Materials and Pavements. The individual standards are also available as downloads on the AASHTO Store, <https://store.transportation.org>. Unless otherwise indicated, these citations refer to the current edition. ASTM materials specifications are also cited.

CHANGED AND DELETED ARTICLES, 2024

SUMMARY OF AFFECTED SECTIONS

The revisions included in the *AASHTO LRFD Bridge Design Specifications*, Tenth Edition affect the following sections:

1. Introduction
2. General Design and Location Features
3. Loads and Load Factors
4. Structural Analysis and Evaluation
5. Concrete Structures
6. Steel Structures
9. Decks and Deck Systems
10. Foundations
11. Walls, Abutments, and Piers
12. Buried Structures and Tunnel Liners
13. Railings
14. Joints and Bearings

SECTION 1 REVISIONS

Changed Articles

The following Articles in Section 1 contain changes or additions to the specifications, the commentary, or both:

1.3.4

Deleted Articles

No Articles were deleted from Section 1.

SECTION 2 REVISIONS

Changed Articles

The following Articles in Section 2 contain changes or additions to the specifications, the commentary, or both:

2.2	2.6.1	2.6.4.3	2.6.4.5	2.6.6.5
2.3.1.2	2.6.2	2.6.4.4.1	2.6.6	2.8
2.3.2.2.1	2.6.3	2.6.4.4.2	2.6.6.1	
2.3.4	2.6.4.1	2.6.4.4.3	2.6.6.3	
2.5.2.1.1	2.6.4.2	2.6.4.4.4	2.6.6.4	

Deleted Articles

No Articles were deleted from Section 2.

SECTION 3 REVISIONS

Changed Articles

The following Articles in Section 3 contain changes or additions to the specifications, the commentary, or both:

3.2	3.4.1	3.5.2	3.6.1.3.1	3.7.4
3.3.1	3.4.4	3.6.1.2.6a	3.6.1.6	3.8.1.1.2
3.3.2	3.4.5	3.6.1.2.6b	3.6.5.1	3.10.1

3.10.2	3.10.4	3.10.9.1	3.11	3.12.4
3.10.2.1	3.10.4.1	3.10.9.2	3.11.5.2	3.12.5
3.10.2.2	3.10.5	3.10.9.3	3.11.6.4	3.14.1
3.10.3	3.10.6	3.10.9.5	3.11.6.4.2	3.16
3.10.3.1	3.10.7.1	3.10.10	3.11.8	B3

Deleted Articles

3.7.5

SECTION 4 REVISIONS

Changed Articles

The following Articles in Section 4 contain changes or additions to the specifications, the commentary, or both:

4.3	4.6.2.7.3	4.6.3.3.2	4.7.4.1	4.7.4.4
4.4	4.6.2.10.1	4.6.3.3.4a	4.7.4.3.1	4.7.4.5
4.5.2.2	4.6.2.10.2	4.6.3.3.4b	4.7.4.3.2b	4.9
4.6.1.2.4b	4.6.2.10.3	4.6.3.3.4c	4.7.4.3.2c	

Deleted Articles

No Articles were deleted from Section 4.

SECTION 5 REVISIONS

Changed Articles

The following Articles in Section 5 contain changes or additions to the specifications, the commentary, or both:

5.2	5.6.4.5	5.9.5.6.5b	5.10.8.2.7	5.12.3.3.8d
5.3	5.6.4.6	5.10.1	5.10.8.4.2a	5.12.3.3.9
5.4.1	5.7.1.5	5.10.2.1	5.10.8.4.3	5.12.3.4.2d
5.4.2.1	5.7.2.1	5.10.2.3	5.10.8.4.5a	5.12.3.4.3
5.4.2.2	5.7.2.3	5.10.3.1.5	5.10.8.4.5c	5.12.5.1
5.4.2.3.1	5.7.2.4	5.10.3.2	5.11.2	5.12.5.2.3

INTRODUCTION

1.1—SCOPE OF THE SPECIFICATIONS

The provisions of these Specifications are intended for the design, evaluation, and rehabilitation of both fixed and movable highway bridges. Mechanical, electrical, and special vehicular and pedestrian safety aspects of movable bridges, however, are not covered. Provisions are not included for bridges used solely for railway, rail-transit, or public utilities. For bridges not fully covered herein, the provisions of these Specifications may be applied, and augmented with additional design criteria where required.

The concepts of safety through redundancy and ductility and of protection against scour and collision are emphasized.

Methods of analysis other than those included in previous Specifications and the modeling techniques inherent in them are included, and their use is encouraged.

The commentary is not intended to provide a complete historical background concerning the development of these or previous Specifications, nor is it intended to provide a detailed summary of the studies and research data reviewed in formulating the provisions of the Specifications. However, references to some of the research data are provided for those who wish to study the background material in depth.

Construction specifications consistent with these design specifications are the *AASHTO LRFD Bridge Construction Specifications*. Unless otherwise specified, the Materials Specifications referenced herein are the *AASHTO Standard Specifications for Transportation Materials and Methods of Sampling and Testing*.

The term “should” indicates a strong preference for a given criterion.

The term “may” indicates a criterion that is usable, but other local and suitably documented, verified, and approved criteria may also be used in a manner consistent with the LRFD approach to bridge design.

1.2—DEFINITIONS

Bridge—Any structure having an opening not less than 20.0 ft that forms part of a highway or that is located over or under a highway.

Collapse—A major change in the geometry of the bridge rendering it unfit for use.

Component—Either a discrete element of the bridge or a combination of elements requiring individual design consideration.

Design—Proportioning and detailing the components and connections of a bridge.

Design Life—Period of time on which the statistical derivation of transient loads is based, which is 75 years for these Specifications.

Ductility—Property of a component or connection that allows inelastic response.

Engineer—Person responsible for the design of the bridge and/or review of design-related field submittals such as erection plans.

Evaluation—Determination of load-carrying capacity of an existing bridge.

Extreme Event Limit States—Limit states relating to events such as earthquakes, ice load, and vehicle and vessel collision, with return periods in excess of the design life of the bridge.

Factored Load—The nominal loads multiplied by the appropriate load factors specified for the load combination under consideration.

Factored Resistance—The nominal resistance multiplied by a resistance factor.

Fixed Bridge—A bridge with a fixed vehicular or navigational clearance.

Force Effect—A deformation, stress, or stress resultant (i.e., axial force, shear force, or torsional or flexural moment) caused by applied loads, imposed deformations, or volumetric changes.

Limit State—A condition beyond which the bridge or component ceases to satisfy the provisions for which it was designed.

Load and Resistance Factor Design (LRFD)—A reliability-based design methodology in which force effects caused by factored loads are not permitted to exceed the factored resistance of the components.

Load Factor—A statistically-based multiplier applied to force effects accounting primarily for the variability of loads, the lack of accuracy in analysis, and the probability of simultaneous occurrence of different loads, but also related to the statistics of the resistance through the calibration process.

Load Modifier—A factor accounting for ductility, redundancy, and the operational classification of the bridge.

Model—An idealization of a structure for the purpose of analysis.

Movable Bridge—A bridge with a variable vehicular or navigational clearance.

Multiple-Load-Path Structure—A structure capable of supporting the specified loads following loss of a main load-carrying component or connection.

Nominal Resistance—Resistance of a component or connection to force effects, as indicated by the dimensions specified in the contract documents and by permissible stresses, deformations, or specified strength of materials.

Owner—Person or agency having jurisdiction over the bridge.

Regular Service—Condition excluding the presence of special permit vehicles, wind exceeding 55 mph, and extreme events, including scour.

Rehabilitation—A process in which the resistance of the bridge is either restored or increased.

Resistance Factor—A statistically-based multiplier applied to nominal resistance accounting primarily for variability of material properties, structural dimensions and workmanship, and uncertainty in the prediction of resistance, but also related to the statistics of the loads through the calibration process.

Service Life—The period of time that the bridge is expected to be in operation.

Service Limit States—Limit states relating to stress, deformation, and cracking under regular operating conditions.

Strength Limit States—Limit states relating to strength and stability during the design life.

1.3—DESIGN PHILOSOPHY

1.3.1—General

Bridges shall be designed for specified limit states to achieve the objectives of constructibility, safety, and serviceability, with due regard to issues of inspectability, economy, and aesthetics, as specified in Article 2.5.

Regardless of the type of analysis used, Eq. 1.3.2.1-1 shall be satisfied for all specified force effects and combinations thereof.

C1.3.1

The limit states specified herein are intended to provide for a buildable, serviceable bridge, capable of safely carrying design loads for a specified lifetime.

The resistance of components and connections is determined, in many cases, on the basis of inelastic behavior, although the force effects are determined by using elastic analysis. This inconsistency is common to most current bridge specifications as a result of incomplete knowledge of inelastic structural action.

1.3.2—Limit States

1.3.2.1—General

Each component and connection shall satisfy Eq. 1.3.2.1-1 for each limit state, unless otherwise specified. For service and extreme event limit states, resistance factors shall be taken as 1.0, except for bolts, for which the provisions of Article 6.5.5 shall apply, and for concrete columns in Seismic Zones 2, 3, and 4, for which the provisions of Articles 5.11.3 and 5.11.4.1.2 shall apply. All limit states shall be considered of equal importance.

$$\sum \eta_i \gamma_i Q_i \leq \phi R_n = R_r \quad (1.3.2.1-1)$$

in which:

For loads for which a maximum value of γ_i is appropriate:

$$\eta_i = \eta_D \eta_R \eta_I \geq 0.95 \quad (1.3.2.1-2)$$

For loads for which a minimum value of γ_i is appropriate:

$$\eta_i = \frac{1}{\eta_D \eta_R \eta_I} \leq 1.0 \quad (1.3.2.1-3)$$

C1.3.2.1

Eq. 1.3.2.1-1 is the basis of LRFD methodology.

Assigning resistance factor $\phi = 1.0$ to all nonstrength limit states is a default, and may be overridden by provisions in other Sections.

Ductility, redundancy, and operational classification are considered in the load modifier η . Whereas the first two directly relate to physical strength, the last concerns the consequences of the bridge being out of service. The grouping of these aspects on the load side of Eq. 1.3.2.1-1 is, therefore, arbitrary. However, it constitutes a first effort at codification. In the absence of more precise information, each effect, except that for fatigue and fracture, is estimated as ± 5 percent, accumulated geometrically. This is a clearly subjective approach, and a rearrangement of Eq. 1.3.2.1-1 may be attained with time. Such a rearrangement might account for improved quantification of ductility, redundancy, and operational classification, and their interactions with system reliability in such an equation.

where:

- γ_i = load factor: a statistically based multiplier applied to force effects
- ϕ = resistance factor: a statistically based multiplier applied to nominal resistance, as specified in Sections 5, 6, 7, 8, 10, 11, and 12
- η_l = load modifier: a factor relating to ductility, redundancy, and operational classification
- η_D = a factor relating to ductility, as specified in Article 1.3.3
- η_R = a factor relating to redundancy, as specified in Article 1.3.4
- η_I = a factor relating to operational classification, as specified in Article 1.3.5
- Q_i = force effect
- R_n = nominal resistance
- R_r = factored resistance: ϕR_n

The influence of η on the girder reliability index, β , can be estimated by observing its effect on the minimum values of β calculated in a database of girder-type bridges. Cellular structures and foundations were not a part of the database; only individual member reliability was considered. For discussion purposes, the girder bridge data used in the calibration of these Specifications was modified by multiplying the total factored loads by $\eta = 0.95, 1.0, 1.05$, and 1.10 . The resulting minimum values of β for 95 combinations of span, spacing, and type of construction were determined to be approximately 3.0, 3.5, 3.8, and 4.0, respectively. In other words, using $\eta > 1.0$ relates to a β higher than 3.5.

A further approximate representation of the effect of η values can be obtained by considering the percent of random normal data less than or equal to the mean value plus $\lambda \sigma$, where λ is a multiplier, and σ is the standard deviation of the data. If λ is taken as 3.0, 3.5, 3.8, and 4.0, the percent of values less than or equal to the mean value plus $\lambda \sigma$ would be about 99.865 percent, 99.977 percent, 99.993 percent, and 99.997 percent, respectively.

The Strength I Limit State in the *AASHTO LRFD Bridge Design Specifications* has been calibrated for a target reliability index of 3.5 with a corresponding probability of exceedance of $2.0E-04$ during the 75-year design life of the bridge. This 75-year reliability is equivalent to an annual probability of exceedance of $2.7E-06$ with a corresponding annual target reliability index of 4.6. Similar calibration efforts for the Service Limit States are underway. Return periods for extreme events are often based on annual probability of exceedance, and caution must be used when comparing reliability indices of various limit states.

1.3.2.2—Service Limit State

The service limit state shall be taken as restrictions on stress, deformation, and crack width under regular service conditions.

C1.3.2.2

The service limit state provides certain experience-related provisions that cannot always be derived solely from strength or statistical considerations.

1.3.2.3—Fatigue and Fracture Limit State

The fatigue limit state shall be taken as restrictions on stress range as a result of a single design truck occurring at the number of expected stress range cycles.

The fracture limit state shall be taken as a set of material toughness requirements of the *AASHTO Materials Specifications*.

C1.3.2.3

The fatigue limit state is intended to limit crack growth under repetitive loads to prevent fracture during the design life of the bridge.

1.3.2.4—Strength Limit State

Strength limit state shall be taken to ensure that strength and stability, both local and global, are provided to resist the specified statistically significant load combinations that a bridge is expected to experience in its design life.

C1.3.2.4

The strength limit state considers stability or yielding of each structural element. If the resistance of any element, including splices and connections, is exceeded, it is assumed that the bridge resistance has been exceeded. In fact, there is significant elastic reserve capacity in almost all multigirder bridges beyond such a load level. The live load cannot be positioned to maximize the force effects on

1.3.2.5—Extreme Event Limit States

The extreme event limit state shall be taken to ensure the structural survival of a bridge during a major earthquake or flood, or when collided with by a vessel, vehicle, or ice floe, possibly under scoured conditions.

1.3.3—Ductility

The structural system of a bridge shall be proportioned and detailed to ensure the development of significant and visible inelastic deformations at the strength and extreme event limit states before failure.

Energy-dissipating devices may be substituted for conventional ductile earthquake resisting systems and the associated methodology addressed in these Specifications or in the *AASHTO Guide Specifications for LRFD Seismic Bridge Design*.

For the strength limit state:

$$\begin{aligned}\eta_D &\geq 1.05 \text{ for nonductile components and connections} \\ &= 1.00 \text{ for conventional designs and details} \\ &\quad \text{complying with these Specifications} \\ &\geq 0.95 \text{ for components and connections for which} \\ &\quad \text{additional ductility-enhancing measures have} \\ &\quad \text{been specified beyond those required by these} \\ &\quad \text{Specifications}\end{aligned}$$

For all other limit states:

$$\eta_D = 1.00$$

all parts of the cross-section simultaneously. Thus, the flexural resistance of the bridge cross-section typically exceeds the resistance required for the total live load that can be applied in the number of lanes available. Extensive distress and structural damage may occur under strength limit state, but overall structural integrity is expected to be maintained.

C1.3.2.5

Extreme event limit states are considered to be unique occurrences that may have severe operational impact and whose return period may be significantly greater than the design life of the bridge.

The Owner may choose to require that the extreme event limit state provide restricted or immediate serviceability in special cases of operational importance of the bridge or transportation corridor.

C1.3.3

The response of structural components or connections beyond the elastic limit can be characterized by either brittle or ductile behavior. Brittle behavior is undesirable because it implies the sudden loss of load-carrying capacity immediately when the elastic limit is exceeded. Ductile behavior is characterized by significant inelastic deformations before any loss of load-carrying capacity occurs. Ductile behavior provides warning of structural failure by large inelastic deformations. Under repeated seismic loading, large reversed cycles of inelastic deformation dissipate energy and have a beneficial effect on structural survival.

If, by means of confinement or other measures, a structural component or connection made of brittle materials can sustain inelastic deformations without significant loss of load-carrying capacity, this component can be considered ductile. Such ductile performance shall be verified by testing.

In order to achieve adequate inelastic behavior, the system should have a sufficient number of ductile members and either:

- joints and connections that are also ductile and can provide energy dissipation without loss of capacity; or
- joints and connections that have sufficient excess strength so as to assure that the inelastic response occurs at the locations designed to provide ductile, energy absorbing response.

Statically ductile but dynamically nonductile response characteristics should be avoided. Examples of this behavior are shear and bond failures in concrete members and loss of composite action in flexural components.

Past experience indicates that typical components designed in accordance with these provisions generally exhibit adequate ductility. Connection and joints require special attention to detailing and the provision of load paths.

The Owner may specify a minimum ductility factor as an assurance that ductile failure modes will be obtained. The factor may be defined as:

$$\mu = \frac{\Delta_u}{\Delta_y} \quad (\text{C1.3.3-1})$$

where:

Δ_u = deformation at ultimate
 Δ_y = deformation at the elastic limit

The ductility capacity of structural components or connections may either be established by full- or large-scale testing or with analytical models based on documented material behavior. The ductility capacity for a structural system may be determined by integrating local deformations over the entire structural system.

The special requirements for energy dissipating devices are imposed because of the rigorous demands placed on these components.

1.3.4—Redundancy

Multiple-load-path and continuous structures should be used unless there are compelling reasons not to use them.

For the strength limit state:

$$\begin{aligned} \eta_R &\geq 1.05 \text{ for nonredundant members} \\ &= 1.00 \text{ for conventional levels of redundancy,} \\ &\quad \text{foundation elements where } \phi \text{ already accounts} \\ &\quad \text{for redundancy as specified in Article 10.5} \\ &\geq 0.95 \text{ for exceptional levels of redundancy beyond} \\ &\quad \text{girder continuity and a torsionally-closed cross-} \\ &\quad \text{section} \end{aligned}$$

C1.3.4

For each load combination and limit state under consideration, member redundancy classification (redundant or nonredundant) should be based upon the member contribution to the bridge safety. Several redundancy measures have been proposed (Frangopol and Nakib, 1991).

Single-cell boxes and single-column bents may be considered nonredundant at the Owner's discretion. For prestressed concrete boxes, the number of tendons in each web should be taken into consideration. For steel cross-sections and fracture-critical considerations, see Section 6.

The *Manual for Bridge Evaluation* (2018) defines bridge redundancy as "the capability of a bridge structural system to carry loads after damage to or the failure of one or more of its members." System factors are provided for post-tensioned segmental concrete box girder bridges in Section 6A.5.11.6 of the Manual.

System reliability encompasses redundancy by considering the system of interconnected components and members. Rupture or yielding of an individual component may or may not mean collapse or failure of the whole structure or system (Nowak, 2000). Reliability indexes for entire systems are a subject of ongoing research and are anticipated to encompass ductility, redundancy, and member correlation.

For all other limit states:

$$\eta_R = 1.00$$

1.3.5—Operational Importance

The Owner may declare a bridge or any structural component and connection thereof to be of operational priority.

For the strength limit state:

$$\begin{aligned}\eta_I &\geq 1.05 \text{ for critical or essential bridges} \\ &= 1.00 \text{ for typical bridges} \\ &\geq 0.95 \text{ for relatively less important bridges.}\end{aligned}$$

For all other limit states:

$$\eta_I = 1.00$$

C1.3.5

Such classification should be done by personnel responsible for the affected transportation network and knowledgeable of its operational needs. The definition of operational priority may differ from Owner to Owner and network to network. Guidelines for classifying critical or essential bridges are as follows:

- Bridges that are required to be open to all traffic once inspected after the design event and be usable by emergency vehicles and for security, defense, economic, or secondary life safety purposes immediately after the design event.
- Bridges that should, as a minimum, be open to emergency vehicles and for security, defense, or economic purposes after the design event, and open to all traffic within days after that event.

Owner-classified bridges may use a value for $\eta < 1.0$ based on *ADTT*, span length, available detour length, or other rationale to use less stringent criteria.

SECTION 2

GENERAL DESIGN AND LOCATION FEATURES

Commentary is opposite the text it annotates.

2.1—SCOPE

Minimum requirements are provided for clearances, environmental protection, aesthetics, geological studies, economy, rideability, durability, constructability, inspectability, and maintainability. Minimum requirements for traffic safety are referenced.

Minimum requirements for drainage facilities and self-protecting measures against water, ice, and waterborne salts are included.

In recognition that many bridge failures have been caused by scour, hydrology and hydraulics are covered in detail.

C2.1

This Section is intended to provide the Designer with sufficient information to determine the configuration and overall dimensions of a bridge.

2.2—DEFINITIONS

Aggradation—General and progressive (long-term) buildup of the longitudinal profile of a channel bed due to sediment deposition, over a relatively long channel length.

Annual Probability of Exceedance—The probability that a specified discharge value will be equaled or exceeded in any year, expressed as a percentage.

Channel—The bed and banks that confine the surface flow of a stream under normal flow conditions.

Clear Zone—An unobstructed, relatively flat area beyond the edge of the traveled way for the recovery of errant vehicles.

Clearance—An unobstructed horizontal or vertical space.

Confluence—The junction of two or more streams.

Contraction Scour—A component of total scour involving the removal of material from the channel bed, banks, and overbank areas due to contraction of the flow area at the bridge which causes an increase in velocity and shear stress on the substrate.

Countermeasure—An action or approach intended to monitor, prevent, delay, or mitigate the severity of hydraulic and/or erosion problems.

Degradation—A general and progressive (long-term) lowering of the channel bed due to erosion, over a relatively long channel length.

Discharge—Volume of water passing through a channel during a given time. A discharge with an annual probability of exceedance of 10 percent or less is also referred to as “flood.” See FHWA’s Hydraulic Engineering Circular No. 18 (HEC-18) Table B.1 (2012a).

Drip Groove—Linear depression in the bottom of components to cause water flowing on the surface to drop.

Five-Hundred-Year Flood—The discharge due to a storm, tide, or both, having a 0.2 percent chance of being equaled or exceeded in any given year; commonly denoted as Q_{500} .

Freeboard—The vertical clearance of the lowest structural member of the bridge superstructure above the water surface elevation.

Hydraulic Design Flood—The discharge and associated probability of exceedance that reflects the desired level of service for a roadway/bridge crossing a watercourse and/or floodplain. This flood drives the capacity design (i.e., size and configuration) of the waterway opening. By definition, the bridge approach roadway or bridge should not be inundated by the water levels produced by this flood.

Local Scour—Removal of material from around piers, abutments, spurs, and embankments caused by an acceleration of flow and resulting vortices induced by obstructions to the flow.

One-Hundred-Year Flood—The discharge due to storm, tide, or both, having a 1 percent chance of being equaled or exceeded in any given year; commonly denoted as Q_{100} .

Overbank Flow—Discharge and associated probability of exceedance that overtops the bank either due to stream stage or due to overland surface water runoff.

Overtopping Flood—The flood described by the probability of exceedance and water surface elevation at which flow occurs over the highway (e.g., over a road embankment, bridge, or culvert), over the watershed divide, or through structure(s) provided for emergency relief.

Regime Change—A change in channel characteristics resulting from such things as changes in imposed flows, sediment loads, or slope.

Relief Bridge—An opening in an embankment on a floodplain to permit passage of overbank flow.

River Training Structure—Any structure constructed in a stream or placed on, adjacent to, or in the vicinity of a streambank to deflect current, induce sediment deposition, induce scour, or in some other way alter the flow and sediment regimens of the stream.

Scour—Erosion of streambed or bank material due to flowing water; often considered as being localized. See “Total Scour.”

Scour Check Flood—A discharge of an annual probability of exceedance selected to estimate scour for an evaluation of the bridge foundation for Extreme Event II limit state.

Scour Design Flood—A discharge of an annual probability of exceedance selected to estimate scour for the design and evaluation of the bridge foundation for strength, service, and Extreme Event I and II limit state events.

Scupper—A device to drain water through the bridge deck, parapet, or barrier.

Sidewalk Width—Unobstructed space for exclusive pedestrian use between barriers or between a curb and a barrier.

Stream—A body of water that may range in size from a large river to a small rill flowing in a channel. By extension, the term is sometimes applied to a natural channel or drainage course formed by flowing water whether it is occupied by water or not.

Superelevation—A tilting of the roadway surface to partially counterbalance the centrifugal forces on vehicles on horizontal curves.

Tide—The periodic rise and fall of the earth’s oceans that results from the effect of the moon and sun acting on a rotating earth.

Total Scour—The summation of long-term degradation, contraction scour, and local scour.

Watershed/Drainage Basin—An area confined by drainage divides, and often having only one outlet for discharge.

Waterway—Any stream, river, pond, lake, or ocean.

Waterway Opening—Width or area of bridge opening at a specified stage, measured normal to the principal flow direction.

2.3—LOCATION FEATURES

2.3.1—Route Location

2.3.1.1—General

The choice of location of bridges shall be supported by analyses of alternatives with consideration given to economic, engineering, social, and environmental concerns as well as costs of maintenance and inspection associated with the structures and with the relative importance of the above-noted concerns.

Attention, commensurate with the risk involved, shall be directed toward providing for favorable bridge locations that:

- fit the conditions created by the obstacle being crossed;
- facilitate practical cost-effective design, construction, operation, inspection, and maintenance;
- provide for the desired level of traffic service and safety; and
- minimize adverse highway impacts.

2.3.1.2—Waterway and Floodplain Crossings

Waterway crossings shall be located with regard to initial capital costs of construction and the optimization of total costs, including river channel training works and the maintenance measures necessary to reduce erosion. Studies of alternative crossing locations should include assessments of:

- the hydrologic, geomorphic, and hydraulic characteristics of the waterway and its floodplain, including channel stability, flood history, and, in estuarine crossings, tidal ranges and cycles;
- the effect of the proposed bridge on flood flow patterns and the resulting scour potential at bridge foundations;
- the potential for creating new or augmenting existing flood hazards; and
- environmental impacts on the waterway and its floodplain.

Bridges and their approaches on floodplains should be located and designed with regard to the goals and objectives of floodplain management, including:

- prevention of uneconomic, hazardous, or incompatible use and development of floodplains;
- avoidance of significant transverse and longitudinal encroachments, where practicable;

C2.3.1.2

Detailed guidance on procedures for evaluating the location of bridges and their approaches on floodplains is contained in Federal Regulations and the Planning and Location Chapter of the *AASHTO Drainage Manual* (see Article C2.6.1). Engineers with knowledge and experience in applying the guidance and procedures in the *AASHTO Drainage Manual* should be involved in location decisions. It is generally safer and more cost-effective to avoid hydraulic problems through the selection of favorable crossing locations than to attempt to minimize the problems at a later time in the project development process through design measures.

Experience at existing bridges should be part of the calibration or verification of hydraulic models, if possible. Evaluation of the performance of existing bridges during past floods is often helpful in selecting the type, size, and location of new bridges.

- minimization of adverse highway impacts and mitigation of unavoidable impacts, where practicable;
- consistency with the intent of the standards and criteria of the National Flood Insurance Program, where applicable;
- long-term aggradation or degradation; and
- commitments made to obtain environmental approvals.

2.3.2—Bridge Site Arrangement

2.3.2.1—General

The location and the alignment of the bridge should be selected to satisfy both on-bridge and under-bridge traffic requirements. Consideration should be given to possible future variations in alignment or width of the waterway, highway, or railway spanned by the bridge.

Where appropriate, consideration should be given to future addition of mass transit facilities or bridge widening.

C2.3.2.1

Although the location of a bridge structure over a waterway is usually determined by other considerations than the hazards of vessel collision, the following preferences should be considered where possible and practical:

- Locating the bridge away from bends in the navigation channel. The distance to the bridge should be such that vessels can line up before passing the bridge, usually eight times the length of the vessel. This distance should be increased further where high currents and winds are prevalent at the site.
- Crossing the navigation channel near right angles and symmetrically with respect to the navigation channel.
- Providing an adequate distance from locations with congested navigation, vessel berthing maneuvers, or other navigation problems.
- Locating the bridge where the waterway is shallow or narrow and the bridge piers could be located out of vessel reach.

2.3.2.2—Traffic Safety

2.3.2.2.1—Protection of Structures

Consideration shall be given to safe passage of vehicles on or under a bridge. The hazard to errant vehicles within the clear zone should be minimized by locating obstacles at a safe distance from the travel lanes.

Pier columns or walls for grade separation structures should be located in conformance with the clear zone concept as contained in the AASHTO *Roadside Design Guide*. Where the practical limits of structure costs, type of structure, volume and design speed of through traffic, span arrangement, skew, and terrain make conformance with the AASHTO *Roadside Design Guide* impractical, the pier or wall should be protected by the use of guardrail or other barrier devices. See Article 3.6.5.

C2.3.2.2.1

The intent of providing structurally independent barriers is to prevent transmission of force effects from the barrier to the structure being protected.

2.3.2.2.2—Protection of Users

Railings shall be provided along the edges of structures conforming to the requirements of Section 13.

All protective structures shall have adequate surface features and transitions to safely redirect errant traffic.

In the case of movable bridges, warning signs, lights, signal bells, gates, barriers, and other safety devices shall be provided for the protection of pedestrian, bicycle, and vehicular traffic. These shall be designed to operate before the opening of the movable span and to remain operational until the span has been completely closed. The devices shall conform to the requirements for “Traffic Control at Movable Bridges” in the *Manual on Uniform Traffic Control Devices* (MUTCD) or as shown on plans.

Where specified by the Owner, sidewalks shall be protected by barriers.

2.3.2.2.3—Geometric Standards

Requirements of *A Policy on Geometric Design of Highways and Streets* (AASHTO) shall either be satisfied or exceptions thereto shall be justified and documented. Width of shoulders and geometry of traffic barriers shall meet the specifications of the Owner.

2.3.2.2.4—Road Surfaces

Road surfaces on a bridge shall be given antiskid characteristics, crown, drainage, and superelevation in accordance with *A Policy on Geometric Design of Highways and Streets* or local requirements.

2.3.2.2.5—Vessel Collisions

Bridge structures shall either be protected against vessel collision forces by fenders, dikes, or dolphins as specified in Article 3.14.15, or shall be designed to withstand collision force effects as specified in Article 3.14.14.

2.3.3—Clearances

2.3.3.1—Navigational

Permits for construction of bridges over navigable waterways shall be obtained from the U.S. Coast Guard, other agencies having jurisdiction, or both. Navigational clearances, both vertical and horizontal, shall be established in cooperation with the U.S. Coast Guard.

C2.3.2.2.2

Protective structures include those that provide a safe and controlled separation of traffic on multimodal facilities using the same right-of-way.

Special conditions, such as curved alignment, impeded visibility, etc., may justify barrier protection, even with low design velocities.

C2.3.2.2.5

The need for dolphin and fender systems can be eliminated at some bridges by judicious placement of bridge piers. Guidance on use of dolphin and fender systems is included in the *AASHTO Highway Drainage Guidelines*, Chapter 7, “Hydraulic Analyses for the Location and Design of Bridges.”

C2.3.3.1

Where bridge permits are required, early coordination should be initiated with the U.S. Coast Guard to evaluate the needs of navigation and the corresponding location and design requirements for the bridge.

Procedures for addressing navigational requirements for bridges, including coordination with the Coast Guard, are set forth in the Code of Federal Regulations, 23 CFR 650, Subpart H, “Navigational Clearances for Bridges,” and 33 USC 401, 491, 511, et seq.

2.3.3.2—Highway Vertical

The vertical clearance of highway structures shall be in conformance with *A Policy on Geometric Design of Highways and Streets* for the functional classification of the highway or exceptions thereto shall be justified. Possible reduction of vertical clearance, due to settlement of an overpass structure, shall be investigated. If the expected settlement exceeds 1.0 in., it shall be added to the specified clearance.

The vertical clearance to sign supports and pedestrian overpasses should be 1.0 ft greater than the highway structure clearance, and the vertical clearance from the roadway to the overhead cross bracing of through-truss structures should not be less than 17.5 ft.

2.3.3.3—Highway Horizontal

The bridge width shall not be less than that of the approach roadway section, including shoulders or curbs, gutters, and sidewalks.

Horizontal clearance under a bridge should meet the requirements of Article 2.3.2.2.1.

No object on or under a bridge, other than a barrier, should be located closer than 4.0 ft to the edge of a designated traffic lane. The inside face of a barrier should not be closer than 2.0 ft to either the face of the object or the edge of a designated traffic lane.

2.3.3.4—Railroad Overpass

Structures designed to pass over a railroad shall be in accordance with standards established and used by the affected railroad in its normal practice. These overpass structures shall comply with applicable federal, state, county, and municipal laws.

Regulations, codes, and standards should, as a minimum, meet the specifications and design standards of the American Railway Engineering and Maintenance of Way Association (AREMA), the Association of American Railroads, and AASHTO.

C2.3.3.2

The specified minimum clearance should include 6.0 in. for possible future overlays. If overlays are not contemplated by the Owner, this requirement may be nullified.

Sign supports, pedestrian bridges, and overhead cross bracings require the higher clearance because of their lesser resistance to impact.

C2.3.3.3

The usable width of the shoulders should generally be taken as the paved width.

The specified minimum distances between the edge of the traffic lane and the fixed object are intended to prevent collision with slightly errant vehicles and those carrying wide loads.

C2.3.3.4

Attention is particularly called to the following chapters in the *Manual for Railway Engineering* (AREMA, 2003):

- Chapter 5—Track, Section 8—Highway/Railway Grade Crossings;
- Chapter 7—Timber Structures;
- Chapter 8—Concrete Structures and Foundations;
- Chapter 15—Steel Structures; and
- Chapter 28—Clearances.

The provisions of the individual railroads and the AREMA *Manual for Railway Engineering* should be used to determine:

- clearances,
- loadings,
- pier protection,
- waterproofing, and
- blast protection.

2.3.4—Environment

The impact of a bridge and its approaches on local communities, historic sites, wetlands, and other aesthetically, environmentally, and ecologically sensitive areas shall be considered. Compliance with state water laws; federal and state regulations concerning encroachment on floodplains, fish, and wildlife habitats; and the provisions of the National Flood Insurance Program shall be assured. Fluvial geomorphology, consequences of riverbed scour, removal of embankment stabilizing vegetation, and, where appropriate, impacts to estuarine tidal dynamics shall be considered.

2.4—FOUNDATION INVESTIGATION

2.4.1—General

A subsurface investigation, including borings and soil tests, shall be conducted in accordance with the provisions of Article 10.4 to provide pertinent and sufficient information for the design of substructure units. The type and cost of foundations should be considered in the economic and aesthetic studies for location and bridge alternate selection.

2.4.2—Topographic Studies

Current topography of the bridge site shall be established via contour maps and photographs. Such studies shall include the history of the site in terms of movement of earth masses, soil and rock erosion, and meandering of waterways.

2.5—DESIGN OBJECTIVES

2.5.1—Safety

The primary responsibility of the Engineer shall be providing for the safety of the public. The Owner may require a design objective other than structural survival for an extreme event.

2.5.1.1—Structural Survival

The structure shall not collapse under the design event. The structure may undergo considerable displacement, settlement, or inelastic deformation. Elements of the structural system may be designated as sacrificial.

2.5.1.2—Limited Serviceability

The structure shall remain stable under designated emergency vehicular live loads.

C2.3.4

Fluvial geomorphology, for purposes of this Section, involves evaluating the streams, potential for aggradation, degradation, or lateral migration.

C2.5.1

Minimum requirements to ensure the structural safety of bridges as conveyances are included in these Specifications. The philosophy of achieving adequate structural safety is outlined in Article 1.3.

C2.5.1.1

The structural repairs may be extensive and require the structure to be replaced or out-of-service for an extended period of time.

C2.5.1.2

Limited displacement, limited plastic deformation in steel members, and spalling in concrete columns may all occur. Sacrificial members may need to be replaced. Structural repairs may be extensive.

2.5.1.3—Immediate Use

The structure may be reopened to all traffic after inspection following an extreme event. All load-carrying members of the structure should remain essentially elastic.

2.5.2—Serviceability**2.5.2.1—Durability***2.5.2.1.1—Materials*

The Contract Documents shall call for quality materials and for the application of high standards of fabrication and erection.

Structural steel shall be self-protecting, or have long-life coating systems or cathodic protection.

Reinforcing bars and prestressing strands in concrete components, which may be expected to be exposed to airborne or waterborne salts, shall be protected by an appropriate combination of epoxy and/or galvanized coating, concrete cover, density, or chemical composition of concrete, including air-entrainment and a nonporous painting of the concrete surface or cathodic protection.

Prestress strands in cable ducts shall be grouted or otherwise protected against corrosion.

Attachments and fasteners used in wood construction shall be of stainless steel, malleable iron, aluminum, or steel that is galvanized, cadmium-plated, or otherwise coated. Wood components shall be treated with preservatives.

Aluminum products shall be electrically insulated from steel and concrete components.

Protection shall be provided to materials susceptible to damage from solar radiation and/or air pollution.

Consideration shall be given to the durability of materials in direct contact with soil, water, or both.

2.5.2.1.2—Self-Protecting Measures

Continuous drip grooves shall be provided along the underside of a concrete deck at a distance not exceeding 10.0 in. from the fascia edges. Where the deck is interrupted by a sealed deck joint, all surfaces of piers and abutments, other than bearing seats, shall have a minimum slope of 5 percent toward their edges. For open deck joints, this minimum slope shall be increased to 15 percent. In the case of open deck joints, the bearings shall be protected against contact with salt and debris.

Wearing surfaces shall be interrupted at the deck joints and shall be provided with a smooth transition to the deck joint device.

Steel formwork shall be protected against corrosion in accordance with the specifications of the Owner.

C2.5.1.3

Minor spalling of concrete columns may occur.

C2.5.2.1.1

The intent of this Article is to recognize the significance of corrosion and deterioration of structural materials to the long-term performance of a bridge. Other provisions regarding durability can be found in Article 5.14.

Other than the deterioration of the concrete deck itself, the single most prevalent bridge maintenance problem is the disintegration of beam ends, bearings, pedestals, piers, and abutments due to percolation of waterborne road salts through the deck joints. Experience appears to indicate that a structurally continuous deck provides the best protection for components below the deck. The potential consequences of the use of road salts on structures with unfilled steel decks and unstressed wood decks should be taken into account.

These Specifications permit the use of discontinuous decks in the absence of substantial use of road salts. Transverse saw-cut relief joints in cast-in-place concrete decks have been found to be of no practical value where composite action is present. Economy, due to structural continuity and the absence of expansion joints, will usually favor the application of continuous decks, regardless of location.

Stringers made simply supported by sliding joints, with or without slotted bolt holes, tend to “freeze” due to the accumulation of corrosion products and cause maintenance problems. Because of the general availability of computers, analysis of continuous decks is no longer a problem.

Experience indicates that, from the perspective of durability, all joints should be considered subject to some degree of movement and leakage.

C2.5.2.1.2

Ponding of water has often been observed on the seats of abutments, probably as a result of construction tolerances and/or tilting. The 15 percent slope specified in conjunction with open joints is intended to enable rains to wash away debris and salt.

In the past, for many smaller bridges, no expansion device was provided at the “fixed joint,” and the wearing surface was simply run over the joint to give a continuous riding surface. As the rotation center of the superstructure is always below the surface, the “fixed joint” actually moves

2.5.2.2—Inspectability

Inspection ladders, walkways, catwalks, covered access holes, and provision for lighting, if necessary, shall be provided where other means of inspection are not practical.

Where practical, access to permit manual or visual inspection, including adequate headroom in box sections, shall be provided to the inside of cellular components and to interface areas, where relative movement may occur.

2.5.2.3—Maintainability

Structural systems whose maintenance is expected to be difficult should be avoided. Where the climatic and/or traffic environment is such that a bridge deck may need to be replaced before the required service life, provisions shall be shown on the contract documents for:

- a contemporary or future protective overlay,
- a future deck replacement, or
- supplemental structural resistance.

Areas around bearing seats and under deck joints should be designed to facilitate jacking, cleaning, repair, and replacement of bearings and joints.

Jacking points shall be indicated on the plans, and the structure shall be designed for jacking forces specified in Article 3.4.3. Inaccessible cavities and corners should be avoided. Cavities that may invite human or animal inhabitants shall either be avoided or made secure.

2.5.2.4—Rideability

The deck of the bridge shall be designed to permit the smooth movement of traffic. On paved roads, a structural transition slab should be located between the approach roadway and the abutment of the bridge. Construction tolerances, with regard to the profile of the finished deck, shall be indicated on the plans or in the specifications or special provisions.

The number of deck joints shall be kept to a practical minimum. Edges of joints in concrete decks exposed to traffic should be protected from abrasion and spalling. The plans for prefabricated joints shall specify that the joint assembly be erected as a unit.

Where concrete decks without an initial overlay are used, consideration should be given to providing an additional thickness of 0.5 in. to permit correction of the deck profile by grinding, and to compensate for thickness loss due to abrasion.

due to load and environmental effects, causing the wearing surface to crack, leak, and disintegrate.

C2.5.2.2

The AASHTO *Guide Specifications for Design and Construction of Segmental Concrete Bridges* require external access hatches with a minimum size of 2.5 ft × 4.0 ft, larger openings at interior diaphragms, and venting by drains or screened vents at intervals of no more than 50.0 ft. These recommendations should be used in bridges designed under these Specifications.

C2.5.2.3

Maintenance of traffic during replacement should be provided either by partial width staging of replacement or by the utilization of an adjacent parallel structure.

Measures for increasing the durability of concrete and wood decks include epoxy coating of reinforcing bars, post-tensioning ducts, and prestressing strands in the deck. Microsilica and/or calcium nitrite additives in the deck concrete, waterproofing membranes, and overlays may be used to protect black steel. See Article 5.14.5 for additional requirements regarding overlays.

2.5.2.5—Utilities

Where required, provisions shall be made to support and maintain the conveyance for utilities.

2.5.2.6—Deformations

2.5.2.6.1—General

Bridges should be designed to avoid undesirable structural or psychological effects due to their deformations. While deflection and depth limitations are made optional, except for orthotropic plate decks, any large deviation from past successful practice regarding slenderness and deflections should be cause for review of the design to determine that it will perform adequately.

If dynamic analysis is used, it shall comply with the principles and requirements of Article 4.7.

C2.5.2.6.1

Service load deformations may cause deterioration of wearing surfaces and local cracking in concrete slabs and in metal bridges that could impair serviceability and durability, even if self-limiting and not a potential source of collapse.

As early as 1905, attempts were made to avoid these effects by limiting the depth-to-span ratios of trusses and girders, and starting in the 1930s, live load deflection limits were prescribed for the same purpose. In a study of deflection limitations of bridges (ASCE, 1958), an ASCE committee found numerous shortcomings in these traditional approaches and noted, for example:

The limited survey conducted by the Committee revealed no evidence of serious structural damage that could be attributed to excessive deflection. The few examples of damaged stringer connections or cracked concrete floors could probably be corrected more effectively by changes in design than by more restrictive limitations on deflection. On the other hand, both the historical study and the results from the survey indicate clearly that unfavorable psychological reaction to bridge deflection is probably the most frequent and important source of concern regarding the flexibility of bridges. However, those characteristics of bridge vibration which are considered objectionable by pedestrians or passengers in vehicles cannot yet be defined.

Since publication of the study, there has been extensive research on human response to motion. It is now generally agreed that the primary factor affecting human sensitivity is acceleration rather than deflection, velocity, or the rate of change of acceleration for bridge structures, but the problem is a difficult subjective one. Thus, there are as yet no simple definitive guidelines for the limits of tolerable static deflection or dynamic motion. Among current specifications, the *Canadian Highway Bridge Design Code* (2014) contains comprehensive provisions regarding vibrations tolerable to humans.

Horizontally-curved steel bridges are subjected to torsion resulting in larger lateral deflections and twisting than tangent bridges. Therefore, rotations due to dead load and thermal forces tend to have a larger effect on the performance of bearings and expansion joints of curved bridges.

For straight skewed steel girder bridges and horizontally-curved steel girder bridges with or without skewed supports, the following additional investigations shall be considered:

- Elastic vertical, lateral, and rotational deflections due to applicable load combinations shall be considered to

ensure satisfactory service performance of bearings, joints, integral abutments, and piers.

- Computed girder rotations at bearings should be accumulated over the Engineer's assumed construction sequence. Computed rotations at bearings shall not exceed the specified rotational capacity of the bearings for the accumulated factored loads corresponding to the stage investigated.
- Camber diagrams shall satisfy the provisions of Article 6.7.2 and may reflect the computed accumulated deflections due to the Engineer's assumed construction sequence.

2.5.2.6.2—Criteria for Deflection

The criteria in this Article shall be considered optional, except for the following:

- The provisions for orthotropic decks shall be considered mandatory.
- The provisions in Article 12.14.5.9 for precast reinforced concrete three-sided structures shall be considered mandatory.
- Metal grid decks and other lightweight metal and concrete bridge decks shall be subject to the serviceability provisions of Article 9.5.2.

In applying these criteria, the vehicular load shall include the dynamic load allowance.

If an Owner chooses to invoke deflection control, the following principles may be applied:

- When investigating the maximum absolute deflection for straight girder systems, all design lanes should be loaded, and all supporting components should be assumed to deflect equally;
- For curved steel box and I-girder systems, the deflection of each girder should be determined individually based on its response as part of a system;
- For composite design, the stiffness of the design cross-section used for the determination of deflection and frequency should include the entire width of the

Bearing rotations during construction may exceed the dead load rotations computed for the completed bridge, in particular at skewed supports. Identification of this temporary situation may be critical to ensure the bridge can be built without damaging the bearings or expansion devices.

C2.5.2.6.2

These provisions permit, but do not encourage, the use of past practice for deflection control. Designers were permitted to exceed these limits at their discretion in the past. Calculated deflections of structures have often been found to be difficult to verify in the field due to numerous sources of stiffness not accounted for in calculations. Despite this, many Owners and Designers have found comfort in the past requirements to limit the overall stiffness of bridges. The desire for continued availability of some guidance in this area, often stated during the development of these Specifications, has resulted in the retention of optional criteria, except for orthotropic decks, for which the criteria are required. Deflection criteria are also mandatory for lightweight decks comprised of metal and concrete, such as filled and partially filled grid decks, and unfilled grid decks composite with reinforced concrete slabs, as provided in Article 9.5.2.

Additional guidance regarding deflection of steel bridges can be found in Wright and Walker (1971).

Additional considerations and recommendations for deflection in timber bridge components are discussed in more detail in Chapters 7, 8, and 9 in Ritter (1990).

For a straight girder system bridge, this is equivalent to saying that the distribution factor for deflection is equal to the number of lanes divided by the number of beams.

For curved steel girder systems, the deflection limit is applied to each individual girder because the curvature causes each girder to deflect differently than the adjacent girder so that an average deflection has little meaning. For curved steel girder systems, the span used to compute the deflection limit should be taken as the arc girder length between bearings.

roadway and the structurally continuous portions of the railings, sidewalks, and median barriers;

- For straight girder systems, the composite bending stiffness of an individual girder may be taken as the stiffness determined as specified above, divided by the number of girders;
- When investigating maximum relative displacements, the number and position of loaded lanes should be selected to provide the worst differential effect;
- The live load portion of Load Combination Service I of Table 3.4.1-1 should be used, including the dynamic load allowance, IM ;
- The live load shall be taken from Article 3.6.1.3.2;
- The provisions of Article 3.6.1.1.2 should apply; and
- For skewed bridges, a right cross-section may be used, and for curved and curved skewed bridges, a radial cross-section may be used.

In the absence of other criteria, the following deflection limits may be considered for steel, aluminum, and/or concrete vehicular bridges:

- Vehicular load, general Span/800,
- Vehicular and pedestrian loads Span/1,000,
- Vehicular load on cantilever arms Span/300, and
- Vehicular and pedestrian loads on cantilever arms Span/375.

For steel I-shaped beams and girders, and for steel box and tub girders, the provisions of Articles 6.10.4.2 and 6.11.4, respectively, regarding the control of permanent deflections through flange stress controls, shall apply. For pedestrian bridges, i.e., bridges whose primary function is to carry pedestrians, bicyclists, equestrians, and light maintenance vehicles, the provisions of Section 5 of AASHTO's *LRFD Guide Specifications for the Design of Pedestrian Bridges* shall apply.

In the absence of other criteria, the following deflection limits may be considered for wood construction:

- Vehicular and pedestrian loads Span/425, and
- Vehicular load on wood planks and panels (extreme relative deflection between adjacent edges) .. 0.10 in.

The following provisions shall apply to orthotropic plate decks:

- Vehicular load on deck plate Span/300,
- Vehicular load on ribs of orthotropic metal decks Span/1000, and

Other criteria may include recognized deflection-frequency-perception requirements such as that specified in the *Canadian Highway Bridge Design Code* (CSA, 2014). Application of the CSA criteria is discussed in Kulicki et al. (2015), including statistical data for live load based on WIM data, a load factor for the HL-93 live load, and a target reliability index.

From a structural viewpoint, large deflections in wood components cause fasteners to loosen and brittle materials, such as asphalt pavement, to crack and break. In addition, members that sag below a level plane present a poor appearance and can give the public a perception of structural inadequacy. Deflections from moving vehicle loads also produce vertical movement and vibrations that annoy motorists and alarm pedestrians (Ritter, 1990).

Excessive deformation can cause premature deterioration of the wearing surface and affect the performance of fasteners, but limits on the latter have not yet been established.

The intent of the relative deflection criterion is to protect the wearing surface from debonding and fracturing due to excessive flexing of the deck.

- Vehicular load on ribs of orthotropic metal decks (extreme relative deflection between adjacent ribs) 0.10 in.

2.5.2.6.3—Optional Criteria for Span-to-Depth Ratios

Unless otherwise specified herein, if an Owner chooses to invoke controls on span-to-depth ratios, the limits in Table 2.5.2.6.3-1, in which S is the slab span length and L is the span length, both in feet, may be considered in the absence of other criteria. Where used, the limits in Table 2.5.2.6.3-1 shall be taken to apply to overall depth unless noted.

For curved steel girder systems, the span-to-depth ratio, L_{as}/D , of each steel girder should not exceed 25 when the specified minimum yield strength of the girder in regions of positive flexure is 50.0 ksi or less, and:

- when the specified minimum yield strength of the girder is 70.0 ksi or less in regions of negative flexure, or
- when hybrid sections satisfying the provisions of Article 6.10.1.3 are used in regions of negative flexure.

For all other curved steel girder systems, L_{as}/D of each steel girder should not exceed the following:

$$\frac{L_{as}}{D} \leq 25 \sqrt{\frac{50}{F_{yt}}} \quad (2.5.2.6.3-1)$$

where:

F_{yt} = specified minimum yield strength of the compression flange (ksi)

D = depth of steel girder (ft)

L_{as} = an arc girder length defined as follows (ft):

- arc span for simple spans;
- 0.9 times the arc span for continuous end-spans;
- 0.8 times the arc span for continuous interior spans.

The 0.10-in. relative deflection limitation is tentative.

C2.5.2.6.3

Traditional minimum depths for constant depth superstructures, contained in previous editions of the *AASHTO Standard Specifications for Highway Bridges*, are given in Table 2.5.2.6.3-1 with some modifications.

A larger preferred minimum girder depth is specified for curved steel girders to reflect the fact that the outermost curved girder receives a disproportionate share of the load and needs to be stiffer. In curved skewed bridges, cross-frame forces are directly related to the relative girder deflections. Increasing the depth and stiffness of all the girders in a curved skewed bridge leads to smaller relative differences in the deflections and smaller cross-frame forces. Deeper girders also result in reduced out-of-plane rotations, which may make the bridge easier to erect.

An increase in the preferred minimum girder depth for curved steel girders not satisfying the conditions specified herein is recommended according to Eq. 2.5.2.6.3-1. In such cases, the girders will tend to be significantly more flexible and less steel causes increased deflections without an increase in the girder depth.

A shallower curved girder might be used if the Engineer evaluates effects such as cross-frame forces and bridge deformations, including girder rotations, and finds the bridge forces and geometric changes within acceptable ranges. For curved composite girders, the recommended ratios apply to the steel girder portion of the composite section.

Table 2.5.2.6.3-1—Traditional Minimum Depths for Constant Depth Superstructures

Superstructure		Minimum Depth (Including Deck)	
Material	Type	Simple Spans	Continuous Spans
Reinforced Concrete	Slabs with Main Reinforcement Parallel to Traffic	$\frac{1.2(S+10)}{30}$	$\frac{S+10}{30} \geq 0.54 \text{ ft}$
	T-Beams	$0.070L$	$0.065L$
	Box Beams	$0.060L$	$0.055L$
	Pedestrian Structure Beams	$0.035L$	$0.033L$
Prestressed Concrete	Slabs	$0.030L \geq 6.5 \text{ in.}$	$0.027L \geq 6.5 \text{ in.}$
	CIP Box Beams	$0.045L$	$0.040L$
	Precast I-Beams	$0.045L$	$0.040L$
	Pedestrian Structure Beams	$0.033L$	$0.030L$
	Adjacent Box Beams	$0.030L$	$0.025L$
Steel	Overall Depth of Composite I-Beam	$0.040L$	$0.032L$
	Depth of I-Beam Portion of Composite I-Beam	$0.033L$	$0.027L$
	Trusses	$0.100L$	$0.100L$

2.5.2.7—Consideration of Future Widening**2.5.2.7.1—Exterior Beams on Girder System Bridges****C2.5.2.7.1**

Unless future widening is virtually inconceivable, the load-carrying capacity of exterior beams shall not be less than the load-carrying capacity of an interior beam.

This provision applies to any longitudinal flexural members traditionally considered to be stringers, beams, or girders.

2.5.2.7.2—Substructure

When future widening can be anticipated, consideration should be given to designing the substructure for the widened condition.

2.5.3—Constructability**C2.5.3**

Constructability issues should include, but not be limited to, consideration of deflection, strength of steel and concrete, and stability during critical stages of construction.

Bridges should be designed in a manner such that fabrication and erection can be performed without undue difficulty or distress and that locked-in construction force effects are within tolerable limits.

When the designer has assumed a particular sequence of construction in order to induce certain stresses under dead load, that sequence shall be defined in the contract documents.

Where there are, or are likely to be, constraints imposed on the method of construction, by environmental

An example of a particular sequence of construction would be where the designer requires a steel girder to be supported while the concrete deck is cast, so that the girder and the deck will act compositely for dead load as well as live load.

considerations or for other reasons, attention shall be drawn to those constraints in the contract documents.

Where the bridge is of unusual complexity, such that it would be unreasonable to expect an experienced Contractor to predict and estimate a suitable method of construction while bidding the project, at least one feasible construction method shall be indicated in the contract documents.

If the design requires some strengthening and/or temporary bracing or support during erection by the selected method, indication of the need thereof shall be indicated in the contract documents.

Details that require welding in restricted areas or placement of concrete through congested reinforcing should be avoided.

Climatic and hydraulic conditions that may affect the construction of the bridge shall be considered.

An example of a complex bridge might be a cable-stayed bridge that has limitations on what it will carry, especially in terms of construction equipment, while it is under construction. If these limitations are not evident to an experienced Contractor, the Contractor may be required to do more prebid analysis than is reasonable. Given the usual constraints of time and budget for bidding, this may not be feasible for the Contractor to do.

This Article does not require the designer to educate a contractor on how to construct a bridge; it is expected that the contractor will have the necessary expertise. Nor is it intended to restrict a contractor from using innovation to gain an edge over the competitors.

All other factors being equal, designs that are self-supporting or use standardized falsework systems are normally preferred to those requiring unique and complex falsework.

Temporary falsework within the clear zone should be adequately protected from traffic.

2.5.4—Economy

2.5.4.1—General

Structural types, span lengths, and materials shall be selected with due consideration of projected cost. The cost of future expenditures during the projected service life of the bridge should be considered. Regional factors, such as availability of material, fabrication, location, shipping, and erection constraints, shall be considered.

C2.5.4.1

If data for the trends in labor and material cost fluctuation are available, the effect of such trends should be projected to the time the bridge will likely be constructed.

Cost comparisons of structural alternatives should be based on long-range considerations, including inspection, maintenance, repair, and/or replacement. The lowest initial cost does not necessarily lead to lowest total cost.

2.5.4.2—Alternative Plans

In instances where economic studies do not indicate a clear choice, the Owner may require that alternative contract plans be prepared and bid competitively. Designs for alternative plans shall be of equal safety, serviceability, and aesthetic value.

Movable bridges over navigable waterways should be avoided to the extent feasible. Where movable bridges are proposed, at least one fixed bridge alternative should be included in the economic comparisons.

2.5.5—Bridge Aesthetics

Bridges should complement their surroundings, be graceful in form, and present an appearance of adequate strength.

C2.5.5

Significant improvements in appearance can often be made with small changes in shape or position of structural members at negligible cost. For prominent bridges, however, additional cost to achieve improved appearance is often justified, considering that the bridge will likely be a feature of the landscape for 75 or more years.

Comprehensive guidelines for the appearance of bridges are beyond the scope of these Specifications. Engineers may refer to such documents as the Transportation Research Board's *Bridge Aesthetics Around the World* (Gottemoeller, 1991) for guidance.

Engineers should seek more pleasant appearance by improving the shapes and relationships of the structural components themselves. The application of extraordinary and nonstructural embellishment should be avoided.

The following guidelines should be considered:

- Alternative bridge designs without piers or with few piers should be studied during the site selection and location stage and refined during the preliminary design stage.
- Pier form should be consistent in shape and detail with the superstructure.
- Abrupt changes in the form of components and structural type should be avoided. Where the interface of different structural types cannot be avoided, a smooth transition in appearance from one type to another should be attained.
- Attention to details, such as deck drain downspouts, should not be overlooked.
- If the use of a through structure is dictated by performance and/or economic considerations, the structural system should be selected to provide an open and uncluttered appearance.
- The use of the bridge as a support for message or directional signing or lighting should be avoided wherever possible.
- Transverse web stiffeners, other than those located at bearing points, should not be visible in elevation.
- For spanning deep ravines, arch-type structures should be preferred.

The most admired modern structures are those that rely for their good appearance on the forms of the structural component themselves:

- Components are shaped to respond to the structural function. They are thick where the stresses are greatest and thin where the stresses are smaller.
- The function of each part and how the function is performed is visible.
- Components are slender and widely spaced, preserving views through the structure.
- The bridge is seen as a single whole, with all members consistent and contributing to that whole; for example, all elements should come from the same family of shapes, such as shapes with rounded edges.
- The bridge fulfills its function with a minimum of material and minimum number of elements.
- The size of each member compared with the others is clearly related to the overall structural concept and the job the component does, and
- The bridge as a whole has a clear and logical relationship to its surroundings.

Several procedures have been proposed to integrate aesthetic thinking into the design process (Gottemoeller, 1991).

Because the major structural components are the largest parts of a bridge and are seen first, they determine the appearance of a bridge. Consequently, engineers should seek excellent appearance in bridge parts in the following order of importance:

- Horizontal and vertical alignment and position in the environment;
- Superstructure type, e.g., arch, girder;
- Pier placement;
- Abutment placement and height;
- Superstructure shape, i.e., haunched, tapered, depth;
- Pier shape;
- Abutment shape;
- Parapet and railing details;
- Surface colors and textures; and
- Ornament.

The Designer should determine the likely position of the majority of viewers of the bridge, then use that information as a guide in judging the importance of various elements in the appearance of the structure.

Perspective drawings of photographs taken from the important viewpoints can be used to analyze the appearance of proposed structures. Models are also useful.

The appearance of standard details should be reviewed to make sure they fit the bridge's design concept.

2.6—HYDROLOGY AND HYDRAULICS

2.6.1—General

Hydrologic, geomorphic, hydraulic, and scour studies and assessments of bridge sites for stream crossings shall be completed as part of the preliminary plan development. The detail of these studies should be commensurate with the importance of and risks associated with the structure.

Temporary structures for the Contractor's use or for accommodating traffic during construction shall be designed with regard to the safety of the traveling public and the adjacent property owners, as well as minimization of impact on floodplain natural resources. The Owner may permit revised design requirements consistent with the intended service period for, and flood hazard posed by, the temporary structure. Contract documents for temporary structures shall delineate the respective responsibilities and risks to be assumed by the highway agency and the Contractor.

Evaluation of bridge design alternatives shall consider stream stability, backwater, flow distribution, stream velocities, scour potential, flood hazards, tidal dynamics where appropriate, and consistency with established criteria for the National Flood Insurance Program.

C2.6.1

The provisions in this Article incorporate improved practices and procedures for the hydraulic design of bridges. Detailed guidance for applying these practices and procedures is contained in the *AASHTO Drainage Manual*. This document contains guidance and references on design procedures and computer software for hydrologic and hydraulic design. It also incorporates guidance and references from the *AASHTO Highway Drainage Guidelines*, which is a companion document to the *AASHTO Drainage Manual*.

Information on the National Flood Insurance Program is contained in 42 USC 4001–4128, the *National Flood Insurance Act* (see also 44 CFR 59 through 77, *National Flood Insurance Program*) and 23 CFR 650, Subpart A, *Location and Hydraulic Design of Encroachment on Floodplains*.

Temporary bridges are described in Article 3.10.10, and have a service life of five years or less. Temporary walls are described in Article 11.5.1, and have a service life of three years or less. Hydraulic design flood, scour design flood, and scour check flood frequencies that may be more applicable for temporary structures are provided in Article C2.6.4.4.2.

Hydrologic, geomorphic, hydraulic, scour, and stream stability studies are concerned with the prediction of flood flows and frequencies and with the complex physical processes involving the actions and interactions of water and soil during the occurrence of predicted flood flows. These studies should be performed by an Engineer with the knowledge and experience to make practical judgments regarding the scope of the studies to be performed and the significance of the results obtained. The design of bridge foundations is best accomplished by an interdisciplinary team of structural, hydraulic, and geotechnical engineers.

The *AASHTO Drainage Manual* (AASHTO, 2014) also contains guidance and references on:

- Design methods for evaluating the accuracy of hydraulic studies, including elements of a data collection plan;
- Guidance on estimating flood flow peaks and volumes, including design standards and other requirements for the design of Interstate highways as per 23 CFR 650, Subpart A, "Encroachments;"
- Procedures or references for analysis of tidal waterways, regulated streams, and urban watersheds;
- Evaluation of stream stability;
- Use of recommended design procedures and software for sizing bridge waterways;
- Location and design of bridges to resist damage from scour and hydraulic loads created by stream current, ice, and debris;
- Calculation of magnitude of long-term degradation, contraction scour, local scour, and countermeasures thereto;
- Design of relief bridges, road overtopping, guide banks, and other river training works; and
- Procedures for hydraulic design of bridge-size culverts.

2.6.2—Site Data

A site-specific data collection plan shall include consideration of:

- Collection of aerial and/or ground survey data for appropriate distances upstream and downstream from the bridge for the main stream channel and its floodplain, including structures on the floodplain;
- Estimation of roughness elements for the stream and the floodplain within the reach of the stream under study;
- Subsurface borings or test pits to collect samples of streambed material to a depth sufficient to ascertain material characteristics for scour analysis and to establish the subsurface stratigraphy;
- Factors affecting water stages, including high water from streams, reservoirs, detention basins, tides, and flood control structures and operating procedures;
- Existing studies and reports, including those conducted in accordance with the provisions of the National Flood Insurance Program or other flood control programs;
- Available historical information on the behavior of the waterway and the performance of the structure during past floods, including observed scour, bank erosion, high water elevation, and structural damage due to the flow of water and debris or ice;
- Possible geomorphic changes in channel form; and
- Estimation of flow misalignment with the crossing, debris potential, and degree of natural contraction at the site.

2.6.3—Hydrologic Analysis

The Owner shall determine the extent of hydrologic studies on the basis of the functional highway classification, the applicable federal and state requirements, and the flood hazards at the site.

The following flood flows shall be investigated, as appropriate, in the hydrologic studies:

- Hydraulic design flood;
- 100-Year flood;
- Scour design flood;
- Scour check flood;
- Known or historic floods, or both;
- Overtopping flood;
- Low or base flow; and
- Spring and tidal range.

Investigation of the effect of sea level rise on tidal ranges shall be specified for structures spanning marine/estuarine resources.

C2.6.2

The assessment of hydraulics necessarily involves many assumptions. Key among these assumptions are the roughness coefficients, projection of long-term flow magnitudes, e.g., the scour check flood, and long-term channel changes such as stream migration and long-term degradation. The discharge (flood) from a given precipitation event can change with the seasons, immediate past weather conditions, and long-term natural and man-made changes in surface conditions. The ability to statistically project flood annual probability of exceedance is a function of the adequacy of the database of past floods, as such projections often change as a result of non-stationarity of climate.

The above factors make the scour evaluation an important, but highly variable, safety criterion that may be expected to be difficult to reproduce unless all of the Designer's original assumptions are used in a post-design scour investigation. Obviously, those original assumptions must be reasonable given the data, conditions, and projections available at the time of the original design.

See HEC-20 (FHWA, 2012c) for additional information and guidance regarding what data to collect and how to use that data for stream assessment.

C2.6.3

The return period of tidal flows should be correlated to the hurricane or storm tide elevations of water as reported in studies by the Federal Emergency Management Agency (FEMA) or other agencies. See FHWA's Hydraulic Engineering Circular No. 25 (HEC-25) (2020) for additional information regarding necessary data for tidal scour assessments.

Particular attention should be given to selecting design and check flood discharges for mixed population flood events. For example, flow in an estuary may have contributions from both tidal and fluvial systems.

The hydraulic design flood is used to satisfy agency design policies and criteria for waterway opening and for setting bridge superstructure and culvert elevations.

The 100-year flood is used for meeting FEMA floodplain management requirements.

The overtopping flood and/or the scour design flood is for assessing risks to highway users and damage to the bridge and its roadway approaches.

The scour check flood is used for assessing the stability of the structure.

The scour design flood and check flood are used for investigating the adequacy of bridge foundations to resist scour.

Known and/or historic floods are used to calibrate hydraulic models.

Low or base flow information is used to evaluate environmental conditions.

The spring and tidal range are used to evaluate estuarine/tidal crossings.

Additional floodplain management design criteria may be applied by Local Floodplain Management Coordinators. Examples include compensatory storage or the addition of a freeboard value above the headwaters from the 100-year flood.

If mixed population flows are dependent on the occurrence of a major meteorological event, such as a hurricane, the relative timing of the individual peak flow events needs to be evaluated and considered in selecting the design discharge for the hydraulic design flood, scour design flood, and scour check flood. This is likely to be the case for flows in an estuary.

If the events tend to be independent, as might be the case for floods in a mountainous region caused by rainfall runoff or snow melt, the Designer should evaluate both events independently and then consider the probability of their occurrence at the same time.

For determining hydraulic and scour design flood frequency conditions for bridges located at or near confluences, refer to *NCHRP Web-Only Document 199: Estimating Joint Probabilities of Design Coincident Flows at Stream Confluences* (Kilgore et al., 2013).

2.6.4—Hydraulic Analysis

2.6.4.1—General

The Engineer shall utilize analytical models and techniques that have been approved by the Owner and that are consistent with the required level of analysis/risk.

2.6.4.2—Stream Stability

Studies shall be carried out to evaluate the stability of the waterway and to assess the impact of construction on the waterway. The following items shall be considered:

- Whether the waterway reach is degrading, aggrading, or in equilibrium;
- For stream crossing near confluences, the effect of the main stream and tributaries on the flood stages, velocities, flow distribution, vertical and lateral movements of the waterway, and the effect of the foregoing conditions on the hydraulic design of the bridge;
- Location of favorable waterway crossing, taking into account whether the stream is straight, meandering, braided, or transitional, or—countermeasures are necessary for protection of the bridge from existing or anticipated future stream conditions;

C2.6.4.2

See HEC-20 (FHWA, 2012c) for additional information and guidance regarding assessment of stream stability.

- The effect of any proposed channel changes;
- The effect of aggregate mining or other operations in the waterway;
- Potential changes in the rates or volumes of flood magnitude due to land use changes;
- The effect of natural geomorphic waterway pattern changes on the proposed structure; and
- The effect of geomorphic changes on existing structures in the vicinity of, and caused by, the proposed structure.

For unstable waterway or flow conditions, special studies shall be carried out to assess future changes to the plan form and profile of the waterway and to determine countermeasures to be incorporated in the design, or at a future time, for the safety of the bridge and approach roadways.

2.6.4.3—Bridge Waterway

The design process for sizing the bridge waterway shall include sensitivity analyses for:

- The evaluation of flood flow patterns in the main channel and floodplain for existing conditions or for proposed conditions,
- The potential changes in flood flow patterns for proposed conditions compared to the existing conditions, and
- The evaluation of trial combinations of highway profiles, alignments, and bridge lengths for consistency with design objectives.

When using existing flood studies, the channel vertical and horizontal alignment, cross sections, discharges, and design parameters shall be verified to ensure they represent current site conditions.

2.6.4.4—Bridge Foundations

2.6.4.4.1—General

The structural, hydraulic, and geotechnical aspects of foundation design shall be coordinated and differences resolved prior to the approval of preliminary plans.

Potential effects of such changes to other existing structures in the vicinity of the project may also need to be considered.

C2.6.4.3

Hydraulic evaluations should take the following into account:

- Increases in flood water surface elevations caused by the bridge,
- Changes in flood flow patterns and velocities in the channel and on the floodplain,
- Hydraulic changes at other bridge openings within the same crossing that are not part of the current project,
- Location of hydraulic controls affecting flow through the structure or long-term stream stability,
- Clearances between the flood-stage and lowest structural member of the superstructure (freeboard) to allow passage of ice and debris,
- Need for protection of bridge foundations and waterway channel bed and banks, and
- Evaluation of capital costs and flood hazards associated with the candidate bridge alternatives through risk assessment or risk analysis procedures.

C2.6.4.4.1

To reduce the vulnerability of the bridge to damage from scour and hydraulic loads, consideration should be given to the following general design concepts:

- Set deck elevations (i.e., bridge finished grades) as high as practical for the given site conditions to minimize inundation by floods. Where bridges are subject to inundation, provide for overtopping of roadway approach sections, and streamline the superstructure to minimize the area subject to hydraulic loads and the collection of ice, debris, and drifts.
- Use relief bridges, guide banks, dikes, and other river training devices to reduce the turbulence and hydraulic forces acting at the bridge abutments.

- Use continuous-span designs. Anchor superstructures to their substructures where subject to the effects of hydraulic loads, buoyancy, ice, or debris impacts or accumulations. Provide for venting and draining of the superstructure.
- Where practical, limit the number of piers in the channel, streamline pier shapes, and align piers with the direction of flood flows. Avoid pier types that collect ice and debris. Locate piers beyond the immediate vicinity of channel banks.
- Locate abutments back from the channel banks where significant problems with ice/debris buildup, scour, or channel instability are anticipated, or where special environmental or regulatory needs must be met, e.g., spanning wetlands.
- Design piers on floodplains as river piers. Locate their foundations at the appropriate depth if there is a likelihood that the stream channel will shift during the life of the structure or that channel cutoffs are likely to occur.
- Where practical, use debris racks or ice booms to stop debris and ice before it reaches the bridge. Where significant ice or debris buildup is unavoidable, its effects should be accounted for in determining scour depths and hydraulic loads.

See HEC-18 (FHWA, 2012a) for additional detailed guidance on pier and abutment location, alignment, and shape within and near the channel.

2.6.4.4.2—Hydraulic Design and Scour Risk

Bridge foundations for new bridges shall be designed to withstand the effects of scour. For the scour design and check floods, the discharge creating the deepest scour corresponding to frequencies up to 100 years, Q_{100} , and up to 500 years, Q_{500} , respectively, shall be used. In lieu of a deterministic approach to calculating maximum scour, a risk-based approach may be adopted that factors in the importance of the structure, consequences of failure, and site experience.

C2.6.4.4.2

Historically, the 100-year flood frequency (or a more frequent overtopping flood if greater scour is generated) has been the minimum standard for the scour design flood; and a flood greater than the scour design flood, the 500-year flood frequency, has been used as the minimum standard for scour check flood. These standards required that foundations for bridges of lesser importance and failure consequence be designed to the same hydraulic standard as bridges of greater importance and failure consequence. Table C2.6.4.2.2-1 provides a summary of recommended minimum flood frequencies for the hydraulic design flood, scour design flood, and scour check flood. The specifications give the bridge Owner the flexibility of implementing risk-based hydraulic design standards, which are based on the importance of the structure and the consequences of failure. The less conservative flood frequencies in the first two rows in the table should only be considered applicable to non-National Highway System (NHS) and temporary bridges. The last two rows in the table are applicable to NHS bridges.

The principles of economic analysis and experience with actual flood damage indicate that it is almost always cost-effective to provide a foundation that will not fail, even from very large events. However, for smaller bridges with lower traveler and economic consequences of failure, it may not be necessary or cost-effective to design the bridge

foundation to withstand the effects of extraordinarily large floods.

See HEC-18 (FHWA, 2012a) for additional background and guidance on risk-based selection of flood frequencies.

See HEC-25 (FHWA, 2020) for additional information regarding risk-based scour considerations for bridges in a tidal environment.

Table C2.6.4.4.2-1—Hydraulic Design Flood Frequencies, and Corresponding Scour Design and Check Flood Frequencies (after FHWA, 2012a).

Hydraulic Design Flood Frequency, Q_D	Scour Design Flood Frequency, Q_S	Scour Check Flood Frequency, Q_C
Q_{10}	Q_{25}	Q_{50}
Q_{25}	Q_{50}	Q_{100}
Q_{50}	Q_{100}	Q_{200}
Q_{100}	Q_{200}	Q_{500}

2.6.4.4.3—Bridge Scour

As required by Article 2.6.4.4.4, scour at bridge foundations, including both intermediate piers and abutments, shall be investigated for two conditions: the scour design flood and scour check flood. For either condition, the streambed material above the total scour elevation at each foundation is assumed to have been removed. The scour design flood and scour check flood shall be based on site-specific risk and functional classification for the roadway in question, consistent with Owner's policies and standards.

Tsunami-induced scour shall be evaluated in conformance to the *AASHTO Guide Specifications for Bridges Subject to Tsunami Effects*.

The greatest scour depth may not occur in the least frequent flood (i.e., greatest discharge) event. If the site conditions, due to ice or debris jams, low tail water conditions near waterway confluences, or other site conditions dictate the use of a more severe scour event for either the scour design, or scour check floods, the Engineer shall use such a flood event. Ice jams or collection of debris can affect the depth of total scour through additional contraction of flow and increased turbulence at the pier; therefore, more frequent flood (i.e., smaller discharge) events or changes in the angle of approach flow due to movement of the channel that results in deeper scour shall be considered to determine the most appropriate scour depth to use for structure foundation design. Whenever total scour depth exposes deep foundation elements, the foundation design shall also consider the potential for damage due to erosion, debris impacts, wood borers, corrosion from exposure to stream currents, or other environmental effects.

With regard to the bridge scour design specifications provided in this Article, the bridge abutment shall be defined to include the structure(s) fully or partially

C2.6.4.4.3

A majority of bridge failures in the United States and elsewhere are the result of water/hydraulics.

The added cost of making a bridge less vulnerable to damage from scour is small in comparison to the total cost of a bridge failure.

The scour design flood and the scour check flood are determined on the basis of the Engineer's judgment of the hydrologic, geomorphic, and hydraulic flow conditions at the site. The recommended procedure is to evaluate flood flows up to the scour design flood and scour check flood to design the foundation for the event expected to cause the deepest total scour at each foundation.

The recommended procedure for determining the total scour depth at bridge foundations is as follows:

- Estimate the long-term channel profile degradation over the service life of the bridge;
- Estimate the long-term channel plan form changes over the service life of the bridge;
- As a design check, adjust the existing channel and floodplain cross-sections upstream and downstream of bridge as necessary to reflect anticipated changes in the channel profile and plan form;
- Determine the combination of existing or likely future conditions and flood events that might be expected to result in the deepest scour for design conditions;
- Determine the magnitude of contraction scour and local scour at piers and abutments; and
- Evaluate the results of the scour analysis, taking into account the variables in the methods used, the available information on the behavior of the waterway, and the performance of existing structures during past floods. Also consider present and anticipated future flow patterns in the channel and its floodplain. Visualize the effect of the bridge on these flow patterns and the effect of the

supported by the abutment foundation, such as the bridge end, abutment wall, curtain and wing walls, and approach slab, and walls critical to bridge stability. Retaining walls supporting the approach fill side slopes that are not critical to the stability of the bridge are not considered part of the bridge abutment for scour considerations.

Shallow foundations (i.e., spread footings) supporting intermediate piers and abutments on soil or erodible rock shall be located so that the top of footing is below scour depths determined for the scour design and scour check floods, and other more frequent flood (discharge) events that could result in deeper scour. In this case, the top of the spread footings shall be located below the total scour depth (i.e., long-term degradation, contraction scour, and local scour) regardless of the presence of scour countermeasures. If the bridge abutment footing is placed on top of a retaining wall, the wall shall be designed for the total scour depth, regardless of the presence of a scour countermeasure.

The potential for stream migration and its effect on scour depth outside of the main channel shall be considered when determining the potential depth of scour at the bridge abutment and interior piers outside of the main channel within the design life of the structure. The potential for scour to undermine the channel slope, resulting in a slope failure, shall be considered when assessing the potential scour depth, including the potential of the scour-induced slope failure to cause lateral loading on the bridge foundations for the abutment as well as the nearby intermediate pier foundations.

Shallow foundations (i.e. spread footings) on scour-resistant rock shall be designed and constructed to maintain the integrity of the supporting rock.

flow on the bridge. Modify the bridge design where necessary to satisfy concerns raised by the scour analysis and the evaluation of the channel plan form.

Foundation designs should be based on the total scour depths estimated by the above procedure, taking into account the design limit states for scour and the applicable load and resistance factors. Where necessary, bridge modifications may include:

- relocation or redesign of piers or abutments to avoid areas of deep scour or overlapping scour holes from adjacent foundation elements,
- addition of guide banks, dikes, or other river training works to provide for smoother flow transitions or to control lateral movement of the channel,
- enlargement of the waterway area, or
- relocation of the crossing to avoid an undesirable location.

Foundations should be designed to withstand the conditions of scour for the scour design flood and the scour check flood. In general, this will result in deep foundations with or without the incorporation of scour countermeasures. The design of the foundations of existing bridges that are being rehabilitated should consider underpinning if scour indicates the need. Riprap and other scour countermeasures may be appropriate if underpinning is not cost-effective.

Deep foundations such as drilled shafts or driven piles, with pile or shaft caps (i.e., footings), should be designed such that the top of the footing is located below the estimated long-term degradation plus contraction scour depth for the scour design flood where practical to minimize obstruction to flood flows and resulting local scour.

Low tail water conditions, occurrence of ice or debris dams, overtopping flood conditions, or changes in the angle of approach flow due to movement of the channel tend to be the most problematic with regard to scour depth. See HEC-18 (FHWA, 2012a) and FHWA TechBrief FHWA-HIF-19-060 (FHWA, 2021) for additional guidance on the determination of the most appropriate scour depth for design.

Procedures for assessing abutment scour for foundation design are provided in HEC-18 (FHWA, 2012a) and summarized in FHWA TechBrief FHWA-HIF-19-007 (FHWA, 2020). If, due to stream migration, an abutment located outside of the main channel could end up within the stream channel, the abutment should be designed for scour as if in the main channel.

Abutment scour calculations typically include the effect of contraction and local scour together. Therefore, there may be no need to add contraction scour to the abutment scour depth calculated as described in HEC-18 (FHWA, 2012a).

Many owners tend to approach abutment scour foundation designs conservatively and simply put the abutment on deep foundations, or at least locate spread footings, if used, below the total scour depth regardless of the abutment location and abutment fill length within the floodplain, and whether or not scour countermeasures are present.

For piers located outside the main channel, and where there is potential for stream migration, the scour depth in the main channel shall also be applied to those piers.

If the top of a pile or shaft cap is located above the scour depth, the foundation design shall additionally address the increased scour depth due to the worsened local scour.

For bridge abutments supported on deep foundations, if a properly designed scour countermeasure, as described in HEC-23 (FHWA, 2009), is present to protect the abutment, the foundation may be designed assuming the soil protected by the scour countermeasure remains in place. In this case, the top of the toe of the scour countermeasure shall be located at or below the depth of long-term degradation plus contraction scour at the scour check flood. If a properly designed countermeasure is not present, the foundation shall be designed assuming that the soil above the total scour depth has been removed.

Deep foundation design, for assessing overburden stress used for bearing resistance calculations, shall consider the effect of the lost soil due to scour as shown in Figure C2.6.4.4.3-1. Similarly, for shallow foundations (i.e., spread footings) located below Point C in the figure, the overburden stress used for assessing bearing resistance after scour should be calculated as shown in this figure.

When fendering or other pier protection systems are used, their effect on pier scour and collection of debris shall be taken into consideration in the design. Since the dimensions of the debris collection are unknown for this scenario, the structural, hydraulic, and geotechnical aspects of the design, based on advanced modeling, local experience, and engineering judgment, shall be coordinated and differences resolved prior to implementation of fendering and other pier protection methodologies.

If scour countermeasures are used, the guidelines summarized in FHWA TechBrief FHWA-HIF-19-007 (FHWA, 2020) and provided in more detail in HEC-23 (FHWA, 2009), should be consulted for countermeasure selection and design.

If scour-induced slope failure of the channel bank and approach fill slope is possible, see HEC-20 (FHWA, 2012c) for guidance.

Additional design requirements for deep foundations with regard to scour are provided in Articles 10.5.5.3.2, C10.5.5.3.2, 10.7.3.6, and C10.7.3.6.

Shown in Figure C2.6.4.4.3-1 is a simplification that can be used to calculate the overburden stress needed for foundation bearing resistance calculations for Service, Strength, and Extreme Event limit states. If a more accurate estimate of overburden stresses is needed, complex three-dimensional modeling would be required, and such modeling may be considered for use in foundation design subject to Owner approval.

Advanced three-dimensional modeling may be needed to assess the effect of fendering or other pier protection systems on scour.

Figure C2.6.4.4.3-1—Illustration of Scour Prism and its Effects on Deep Foundations (adapted FHWA-NHI-18-024, GEC010—*Drilled Shafts Manual: Construction Procedures and Methods*)

2.6.4.4.4—Change in Foundation Conditions due to Scour

C2.6.4.4.4

The consequences of changes in foundation conditions resulting from the scour design and scour check floods shall be considered at service, strength, and Extreme Events I and II limit states. The design shall consider foundation conditions with and without scour, and with aggradation. For the foundation conditions with scour, the combination of the effects of long-term degradation, contraction scour, and local scour for different limit states shall be according to Table 2.6.4.4.4-1. The effects of changes in foundation condition should also consider stream migration as specified in Article 2.6.4.4.3.

Scour is not a force effect per se, but the change in conditions of the substructure may significantly alter the consequences of force effects acting on structures.

The scour combination for Extreme Event I limit state has been adapted from Article C3.4.1 in previous editions of the *AASHTO LRFD Bridge Design Specifications*.

The scour combination for Extreme Event II limit state for vessel collision force, CV , has been adapted from the *AASHTO Guide Specifications and Commentary for Vessel Collision Design of Highway Bridges* (2009).

Table 2.6.4.4.4-1—Combination of Scour Components for Different Limit States (in %)

Limit State	Degradation	Contraction Scour	Local Scour	Flood
Service	100	100	100	Scour Design Flood
Strength	100	100	100	Scour Design Flood
Extreme Event I	50	50	50	Scour Design Flood
Extreme Event II (Case A for CV and for IC)	50	50	50	Scour Design Flood
Extreme Event II (Case B for CV)	50	0	0	Yearly Mean Discharge
Extreme Event II (Check Flood)	100	100	100	Scour Check Flood

Note: The design shall also consider foundation conditions without scour, or when applicable with aggradation.

2.6.4.5—Roadway Approaches to Bridge

The design of the bridge shall be coordinated with the design of the roadway approaches to the bridge on the floodplain so that the entire flood flow pattern is developed and analyzed as a single, interrelated entity. Where roadway approaches on the floodplain obstruct overbank flow, the highway segment within the floodplain limits shall be designed to minimize flood hazards.

Where diversion of flow to another watershed occurs as a result of backwater and obstruction of flood flows, an evaluation of the design shall be carried out to ensure compliance with legal requirements in regard to flood hazards in the other watershed.

Retaining walls shall be designed for scour as specified in Articles 11.6.3.4, 11.7.2.3, 11.10.1, and 11.10.2.2.

The potential for stream migration and the effects of scour on the bridge approach embankment or retaining wall shall be evaluated.

If scour countermeasures are used to protect the base of the retaining wall, the upper surface of the scour countermeasure toe shall be located at or below the long-term degradation plus contraction scour elevation for the scour design flood. In this case, the base of the wall shall be below the top of the scour countermeasure.

C2.6.4.5

Highway embankments on floodplains serve to redirect overbank flow, causing it to flow generally parallel to the embankment and return to the main channel at the bridge. Roadway embankment and retaining wall designs should include countermeasures where necessary to limit damage caused by overbank flow parallel to the embankment. Such countermeasures may include:

- relief bridges, culverts, or other structural openings;
- retarding the velocity of the overbank flow by promoting growth of trees and shrubs on the floodplain and highway embankment within the highway right-of-way or constructing small dikes along the highway embankment;
- protecting fill slopes subject to erosive velocities by use of riprap or other erosion protection materials on highway fills and spill-through abutments;
- where overbank flow is large, use guide banks to protect abutments of main channel and relief bridges from turbulence and resulting scour;
- regular inspection of embankments and/or walls in these locations, particularly following flood events; and
- providing additional floodplain conveyance to reduce velocities and shear stresses.

Additional information and design guidelines on scour countermeasures are provided in HEC-23 (FHWA, 2009) and FHWA TechBrief FHWA-HIF-19-007 (FHWA, 2020).

Although overtopping may result in failure of the embankment, this consequence is preferred to failure of the bridge. The low point of the overtopping section should not be located immediately adjacent to the bridge, because its failure at this location could cause damage to the bridge abutment. If the low point of the overtopping section must be located close to the abutment, due to geometric constraints, the scouring effect of the overtopping flow should be considered in the design of the abutment. Design studies for overtopping should also include evaluation of any flood hazards created by changes to existing flood flow patterns or by flow concentrations in the vicinity of developed properties.

Bridge approach embankment slopes exposed to scour should be protected with properly designed scour countermeasures designed in accordance with HEC-23 (FHWA, 2009) and FHWA TechBrief FHWA-HIF-19-007 (FHWA, 2020) where possible, considering any regulatory requirements.

The risk of bridge approach fill failure due to scour may be an acceptable risk as the approach fill typically can be replaced quickly to restore access to the bridge crossing. The impact of such approach fill loss to bridge approach structures such as wing walls, bridge approach slabs, and small (i.e., short in height and length) retaining walls that support the approach embankment side slopes will need to be considered. The Owner should consider the importance of the route and the safety risk to the public, as well as the economic impacts to travelers with the temporary loss of the approach fill. This is especially important if significant stream migration risk is not low, as much more of the embankment could be affected, or, as illustrated in HEC-18 (FHWA, 2012a), Figure 8.7(c), the bridge abutment could become like an intermediate bridge pier with regard to increased scour depth due to local and contraction scour.

The length of bridge approach embankment or wall relative to the bridge abutment location that can be affected by scour, and how deep the scour is likely to occur, will depend on several factors, including the length of the approach embankment within the floodplain and the potential for stream migration. For the portion of the approach retaining wall outside the potential limits of stream migration, scour due to long-term degradation is no longer applicable, and only contraction scour and local scour should be considered to locate the wall footing or wall base.

2.6.5—Culvert Location, Length, and Waterway Area

In addition to the provisions of Articles 2.6.3 and 2.6.4, the following conditions should be considered:

- passage of fish and wildlife,
- effect of high outlet velocities and flow concentrations on the culvert outlet, the downstream channel, and adjacent property,
- buoyancy effects at culvert inlets,
- traffic safety, and
- the effects of high tail water conditions as may be caused by downstream controls or storm tides.

2.6.6—Roadway Drainage

2.6.6.1—General

The bridge deck and its highway approaches shall be designed to provide safe and efficient conveyance of surface runoff from the traveled way in a manner that minimizes damage to the bridge and maximizes the safety of passing vehicles. Transverse drainage of the deck, including roadway, bicycle paths, and pedestrian walkways, shall be achieved by providing a cross slope or

C2.6.5

The discussion of site investigations and hydrologic and hydraulic analyses for bridges is generally applicable to large culvert installations classified as bridges.

The use of safety grates on culvert ends to protect vehicles that run off the road is generally discouraged for large culverts, including those classified as bridges, because of the potential for clogging and subsequent unexpected increase in the flood hazard to the roadway and adjacent properties. Preferred methods of providing for traffic safety include the installation of barriers or the extension of the culvert ends to increase the vehicle recovery zone at the site.

C2.6.6.1

Where feasible, bridge decks should be watertight and all of the deck drainage should be carried to the ends of the bridge.

A longitudinal gradient on bridges should be maintained. Zero gradients and sag vertical curves should be avoided. The minimum recommended longitudinal gradient is 0.3 percent. However, preferably, the longitudinal gradient should not be

superelevation sufficient for positive drainage. For wide bridges with more than three lanes in each direction, special design of bridge deck drainage and/or special rough road surfaces may be needed to reduce the potential for hydroplaning. Water flowing downgrade in the roadway gutter section shall be intercepted and not permitted to run onto the bridge. Drains at bridge ends shall have sufficient capacity to carry all contributing runoff.

less than 0.5 percent. The transverse drainage of the bridge deck should be accommodated by providing a suitable roadway cross slope, typically 2 percent. Design of the bridge deck and the approach roadway drainage systems should be coordinated.

Under certain conditions, open bridge railings may be desirable for improved discharge of surface runoff from bridge decks. A longitudinal gradient on bridges should be maintained. Zero gradients and sag vertical curves should be avoided. The minimum recommended longitudinal gradient is 0.2 percent. Design of the bridge deck and the approach roadway drainage systems should be coordinated.

In those unique environmentally sensitive instances where it is not possible to discharge into the underlying waterway, consideration should be given to conveying the water longitudinally, either on or below the deck, and discharging it into appropriate facilities on natural ground at the bridge end.

2.6.6.2—Design Storm

The design storm for bridge deck drainage shall not be less than the storm used for design of the pavement drainage system of the adjacent roadway, unless otherwise specified by the Owner.

2.6.6.3—Type, Size, and Number of Drains

The number of deck drains should be kept to a minimum consistent with hydraulic requirements.

In the absence of other applicable guidance, for bridges where the highway design speed is less than 45 mph, the size and number of deck drains should be such that the spread of deck drainage does not encroach on more than one-half the width of any designated traffic lane. For bridges where the highway design speed is equal to or greater than 45 mph, the spread of deck drainage should not encroach on any portion of the designated traffic lanes. Gutter flow should be intercepted at cross slope transitions to prevent flow across the bridge deck.

Scuppers or inlets of a deck drain shall be hydraulically efficient and accessible for cleaning.

2.6.6.4—Discharge from Deck Drains

Deck drains shall be designed and located such that surface water from the bridge deck or road surface is directed away from the bridge superstructure elements and the substructure.

If the Owner has no specific requirements for controlling the discharge from drains and pipes, consideration should be given to:

- a minimum 4.0-in. projection below the lowest adjacent superstructure component,
- location of pipe outlets such that a 45-degree cone of splash will not touch structural components,
- use of scuppers or slots in parapets wherever practical and permissible,

C2.6.6.3

For further guidance or design criteria on bridge deck drainage, see the *AASHTO Drainage Manual* (AASHTO 2014), AASHTO's *A Policy on the Geometric Design of Highways and Streets* (AASHTO, 2018), and FHWA publications *Hydraulic Design of Safe Bridges*, HDS-7 (FHWA, 2012b), *Design of Bridge Deck Drainage*, HEC-21 (FHWA, 1993), and *Urban Drainage Design Manual*, HEC-22 (FHWA, 2009).

The minimum internal dimension of a downspout should not normally be less than 6.0 in., but not less than 8.0 in. where ice accretion on the bridge deck is expected.

C2.6.6.4

Consideration should be given to the effect of drainage systems on bridge aesthetics; however, safety for the traveling public is of primary importance.

For bridges where scuppers are not feasible, attention should be given to the design of the outlet piping system to:

- use of bends not greater than 45 degrees, and
- use of cleanouts.

Runoff from bridge decks and deck drains shall be disposed of in a manner consistent with environmental and safety requirements.

2.6.6.5—Drainage of Structures

Cavities in structures where there is a likelihood for entrapment of water shall be drained at their lowest point. Decks and wearing surfaces shall be designed to prevent the ponding of water, especially at deck joints. For bridge decks with nonintegral wearing surfaces or stay-in-place forms, consideration shall be given to the evacuation of water that may accumulate at the interface.

2.7—BRIDGE SECURITY

2.7.1—General

An assessment of the priority of a bridge should be conducted during the planning of new bridges and during rehabilitation of existing bridges. This should take into account the social/economic impact of the loss of the bridge, the availability of alternate routes, and the effect of closing the bridge on the security/defense of the region.

For bridges deemed critical or essential, a formal vulnerability study should be conducted, and measures to mitigate the vulnerabilities should be considered for incorporation into the design.

2.7.2—Design Demand

Bridge Owners should establish criteria for the size and location of the threats to be considered in the analysis of bridges for security. These criteria should take into account the type, geometry, and priority of the structure being considered. The criteria should also consider multi-tier threat sizes and define the associated level of structural performance for each tier.

- minimize clogging and other maintenance problems and
- minimize the intrusive effect of the piping on the bridge symmetry and appearance.

Scuppers should be avoided where runoff creates problems with traffic, rail, or shipping lanes. Riprap or pavement should be provided under the free fall from scuppers to prevent erosion.

C2.6.6.5

Weep holes in concrete decks and drain holes in stay-in-place forms can be used to permit the egress of water.

If possible, scuppers should not be placed through box beams and other structural components as any leakage could have adverse structural consequences.

C2.7.1

At the time of this writing, there are no uniform procedures for assessing the priority of a bridge to the social/economic impact and defense/security of a region. Work is being done to produce a uniform procedure to prioritize bridges for security.

In the absence of uniform procedures, some states have developed procedures that incorporate their own security prioritization methods which, while similar, differ in details. In addition, procedures to assess bridge priority were developed by departments of transportation in some states to assist in prioritizing seismic rehabilitation. The procedures established for assessing bridge priority may also be used in conjunction with security considerations.

Guidance on security strategies and risk reduction may be found in the following documents: Science Applications International Corporation (2002), The Blue Ribbon Panel on Bridge and Tunnel Security (2003), Winget (2003), Jenkins (2001), Abramson et al. (1999), and Williamson (2006).

C2.7.2

It is not possible to protect a bridge from every conceivable threat. The most likely threat scenarios should be determined based on the bridge structural system and geometry and the identified vulnerabilities. The most likely attack scenarios will minimize the attacker's required time on target, possess simplicity in planning and execution, and have a high probability of achieving maximum damage.

The level of acceptable damage should be proportionate to the size of the attack. For example, linear behavior and/or local damage should be expected under a small-size attack,

Design demands should be determined from analysis of a given size design threat, taking into account the associated performance levels. Given the demands, a design strategy should be developed and approved by the Bridge Owner.

while significant permanent deformations and significant damage and/or partial failure of some components should be acceptable under larger size attacks.

The level of threat and the operational classification of the bridge should be taken into account when determining the level of analysis to be used in determining the demands. Approximate methods may be used for low-force threats and low-importance bridges, while more sophisticated analyses should be used for high-force threats to priority bridges.

SECTION 3

LOADS AND LOAD FACTORS

Commentary is opposite the text it annotates.

3.1—SCOPE

This Section specifies minimum requirements for loads and forces, the limits of their application, load factors, and load combinations used for the design of new bridges. The load provisions may also be applied to the structural evaluation of existing bridges.

Where multiple performance levels are provided, the selection of the design performance level is the responsibility of the Owner.

A minimum load factor is specified for force effects that may develop during construction. Additional requirements for construction of segmental concrete bridges are specified in Article 5.12.5.

C3.1

This Section includes, in addition to traditional loads, the force effects due to collisions, earthquakes, and settlement and distortion of the structure.

Vehicle and vessel collisions, earthquakes, and aeroelastic instability develop force effects that are dependent upon structural response. Therefore, such force effects cannot be determined without analysis and/or testing.

With the exception of segmental concrete bridges, construction loads are not provided, but the Designer should obtain pertinent information from prospective contractors.

3.2—DEFINITIONS

Active Earth Pressure—Lateral pressure resulting from the retention of the earth by a structure or component that is tending to move away from the soil mass.

Active Earth Wedge—Wedge of earth with a tendency to become mobile if not retained by a structure or component.

Aeroelastic Vibration—Periodic, elastic response of a structure to wind.

Apparent Earth Pressure (AEP)—Lateral pressure distribution for anchored walls constructed from the top down.

Axle Unit—Single axle or tandem axle.

Berm—An earthwork used to redirect or slow down impinging vehicles or vessels and to stabilize fill, embankment, or soft ground and cut slopes.

Centrifugal Force—A lateral force resulting from a change in the direction of a vehicle's movement.

Damper—A device that transfers and reduces forces between superstructure elements, superstructure and substructure elements, or both, while permitting thermal movements. The device provides damping by dissipating energy under seismic, braking, or other dynamic loads.

Deep Draft Waterways—A navigable waterway used by merchant ships with loaded drafts of 14–60+ ft.

Design Lane—A notional traffic lane positioned transversely on the roadway.

Design Thermal Movement Range—The structure movement range resulting from the difference between the maximum design temperature and minimum design temperature as defined in Article 3.12.

Design Water Depth—Depth of water at mean high water.

Distortion—Change in structural geometry.

Dolphin—Protective object that may have its own fender system and that is usually circular in plan and structurally independent from the bridge.

Downdrag—the downward movement (settlement) of a deep foundation element in response to drag load.

Drag Load—the load applied to a deep foundation element due to settlement of the adjacent ground relative to the deep foundation element.

Dynamic Load Allowance—An increase in the applied static force effects to account for the dynamic interaction between the bridge and moving vehicles.

Equivalent Fluid—A notional substance whose density is such that it would exert the same pressure as the soil it is seen to replace for computational purposes.

Exposed—A condition in which a portion of a bridge's substructure or superstructure is subject to physical contact by any portion of a colliding vessel's bow, deck house, or mast.

Extreme—A maximum or a minimum.

Fender—Protection hardware attached to the structural component to be protected or used to delineate channels or to redirect aberrant vessels.

Frazil Ice—Ice resulting from turbulent water flow.

Global—Pertinent to the entire superstructure or to the whole bridge.

Influence Surface—A continuous or discretized function over a bridge deck whose value at a point, multiplied by a load acting normal to the deck at that point, yields the force effect being sought.

Knot—A velocity of 1.1508 mph.

Lane—The area of deck receiving one vehicle or one uniform load line.

Lever Rule—The statical summation of moments about one point to calculate the reaction at a second point.

Liquefaction—The loss of shear strength in a saturated soil due to excess hydrostatic pressure. In saturated, cohesionless soils, such a strength loss can result from loads that are applied instantaneously or cyclically, particularly in loose fine to medium sands that are uniformly graded.

Load—The effect of acceleration, including that due to gravity, imposed deformation, or volumetric change.

Local—Pertinent to a component or subassembly of components.

Mode of Vibration—A shape of dynamic deformation associated with a frequency of vibration.

Navigable Waterway—A waterway determined by the U.S. Coast Guard as being suitable for interstate or foreign commerce, as described in 33 CFR 205–25.

Neutral Plane—The location along a deep foundation where the total permanent structure loads (including drag load) is in equilibrium with the total side and tip resistance.

Nominal Load—An arbitrarily selected design load level.

Normally Consolidated Soil—A soil for which the current effective overburden pressure is the same as the maximum pressure that has been experienced.

Overconsolidated Soil—A soil that has been under greater overburden pressure than currently exists.

Overall Stability—Stability of the entire retaining wall or abutment structure and is determined by evaluating potential slip surfaces located outside of the whole structure.

Overconsolidation Ratio—Ratio of the maximum preconsolidation pressure to the overburden pressure.

Passive Earth Pressure—Lateral pressure resulting from the earth's resistance to the lateral movement of a structure or component into the soil mass.

Permanent Loads—Loads and forces that are, or are assumed to be, either constant upon completion of construction or varying only over a long time interval.

Permit Vehicle—Any vehicle whose right to travel is administratively restricted in any way due to its weight or size.

Reliability Index—A quantitative assessment of safety expressed as the ratio of the difference between the mean resistance and mean force effect to the combined standard deviation of resistance and force effect.

Restrainers—A system of high-strength cables or rods that transfers forces between superstructure elements, superstructure and substructure elements, or both under seismic or other dynamic loads after an initial slack is taken up, while permitting thermal movements.

Roadway Width—Clear space between barriers, curbs, or both.

Setting Temperature—A structure's average temperature, which is used to determine the dimensions of a structure when a component is added or set in place.

Shallow Draft Waterways—A navigable waterway used primarily by barge vessels with loaded drafts of less than 9–10 ft.

Shock Transmission Unit (STU)—A device that provides a temporary rigid link between superstructure elements, superstructure and substructure elements, or both, under seismic, braking, or other dynamic loads, while permitting thermal movements.

Structurally Continuous Barrier—A barrier, or any part thereof, that is interrupted only at deck joints.

Substructure—Structural parts of the bridge that support the horizontal span.

Superstructure—Structural parts of the bridge that provide the horizontal span.

Surcharge—A load used to model the weight of earth fill or other loads applied to the top of the retained material.

Tandem—Two closely spaced axles, usually connected to the same under-carriage, by which the equalization of load between the axles is enhanced.

Transient Loads—Loads and forces that can vary over a short time interval relative to the lifetime of the structure.

Tonne—2.205 kip.

Wall Friction Angle—An angle whose arctangent represents the apparent friction between a wall and a soil mass.

Wheel—Single or dual tire at one end of an axle.

Wheel Line—A transverse or longitudinal grouping of wheels.

3.3—NOTATION

3.3.1—General

A	=	plan area of ice floe (ft ²); depth of temperature gradient (in.) (C3.9.2.3) (3.12.3)
AEP	=	apparent earth pressure for anchored walls (ksf) (3.4.1)
AF	=	annual frequency of bridge element collapse (number/year) (C3.14.4)
AF_{BC}	=	the expected annual frequency of bridge collapse (C3.6.5.1)
A_{LL}	=	rectangular area at depth H (ft ²) (3.6.1.2.6b)
a	=	length of uniform deceleration at braking (ft); truncated distance (ft); average bow damage length (ft) (C3.6.4) (C3.9.5) (C3.14.9)
a_B	=	bow damage length of standard hopper barge (ft) (3.14.11)
a_s	=	bow damage length of ship (ft) (3.14.9)
A_S	=	design response spectral acceleration coefficient, S_a , at a period of zero s (3.10.4.1) (3.10.9.1)

AR	=	horizontal curve away from fixed object (C3.6.5.1)
B	=	notional slope of backfill (degrees) (3.11.5.8.1)
B'	=	equivalent footing width (ft) (3.11.6.3)
B_e	=	width of excavation (ft) (3.11.5.7.2b)
B_M	=	beam (width) for barge, barge tows, and ship vessels (ft) (C3.14.5.1)
B_p	=	width of bridge pier (ft) (3.14.5.3)
BR	=	vehicular braking force; base rate of vessel aberrancy (3.3.2) (3.14.5.2.3)
b	=	braking force coefficient; width of a discrete vertical wall element (ft) (C3.6.4) (3.11.5.6)
b_f	=	width of applied load or footing (ft) (3.11.6.3)
C	=	coefficient to compute centrifugal forces; constant for terrain conditions in relation to wind approach (3.6.3) (C3.8.1.1)
C_a	=	coefficient for force due to crushing of ice (3.9.2.2)
C_D	=	drag coefficient (s^2 lbs./ft ⁴) (3.7.3.1)
C_H	=	hydrodynamic mass coefficient (3.14.7)
C_L	=	lateral drag coefficient (C3.7.3.1)
C_n	=	coefficient for nose inclination to compute F_b (3.9.2.2)
c	=	soil cohesion (ksf) (3.11.5.4)
c_f	=	distance from back of a wall face to the front of an applied load or footing (ft) (3.11.6.3)
D	=	depth of embedment for a permanent nongravity cantilever wall with discrete vertical wall elements (ft) (3.11.5.6)
D_B	=	bow depth (ft) (C3.14.5.1)
D_E	=	minimum depth of earth cover (ft) (3.6.2.2)
D_i	=	inside diameter or clear span of the culvert (in.); size of the critical component of the pier in direction i where size is either the diameter of the critical circular column or the smallest cross-sectional dimension of a rectangular column (3.6.1.2.6b) (C3.6.5.1)
D_o	=	calculated embedment depth to provide equilibrium for nongravity cantilevered with continuous vertical elements by the simplified method (ft) (3.11.5.6)
DWT	=	size of vessel based on deadweight tonnage (tonne) (C3.14.1)
D_1	=	effective width of applied load at any depth (ft) (3.11.6.3)
d	=	depth of potential base failure surface below base of excavation (ft); horizontal distance from the back of a wall face to the centerline of an applied load (ft) (3.11.5.7.2b) (3.11.6.3)
d_c	=	total thickness of cohesive soil layers in the top 100 ft (3.10.3.1)
d_s	=	total thickness of cohesionless soil layers in the top 100 ft (3.10.3.1)
E	=	Young's modulus (ksf) (C3.9.5)
E_B	=	deformation energy (kip-ft) (C3.14.11)
e'	=	eccentricity of load on footing (ft) (3.11.6.3)
F	=	longitudinal force on pier due to ice floe (kip); force required to fail an ice sheet (kip/ft); force at base of nongravity cantilevered wall required to provide force equilibrium (kip/ft) (3.9.2.2) (C3.9.5) (3.11.5.6)
F_b	=	horizontal force due to failure of ice flow due to bending (kip) (3.9.2.2)
F_c	=	horizontal force due to crushing of ice (kip) (3.9.2.2)
F_t	=	transverse force on pier due to ice flow (kip) (3.9.2.4.1)
F_v	=	vertical ice force due to adhesion (kip) (3.9.5)
F_1	=	lateral force due to earth pressure (kip/ft) (3.11.6.3)
F_2	=	lateral force due to traffic surcharge (kip/ft) (3.11.6.3)
f	=	constant applied in calculating the coefficient C used to compute centrifugal forces, taken equal to $4/3$ for load combinations other than fatigue and 1.0 for fatigue (3.6.3)
f_{ACC}	=	major access modification factor (C3.6.5.1)
f'_c	=	specified compressive strength of concrete for use in design (ksi) (3.5.1)
f_G	=	grade modification factor (C3.6.5.1)
f_{HC}	=	horizontal curve radius modification factor (C3.6.5.1)
f_{LN}	=	lanes in one direction modification factor (C3.6.5.1)
f_{LW}	=	lane width modification factor (C3.6.5.1)
f_{PSL}	=	posted speed limit modification factor (C3.6.5.1)
G	=	roadway grade (percent); gust effect factor (C3.6.5.1) (3.8.1.2.1)
g	=	gravitational acceleration (ft/s ²) (3.6.3)
H	=	depth of fill over culvert (ft); ultimate bridge element strength (kip); final height of retaining wall (ft); total excavation depth (ft); resistance of bridge component to a horizontal force (kip) (3.6.1.2.6b) (C3.11.1) (3.11.5.7.1) (3.14.5.4)

H_{int-p}	=	axle interaction depth parallel to culvert span (ft) (3.6.1.2.6b)
H_{int-t}	=	wheel interaction depth transverse to culvert span (ft) (3.6.1.2.6b)
H_L	=	depth of barge head-block on its bow (ft) (3.14.14.1)
H_{n+1}	=	distance from base of excavation to lowermost ground anchor (ft) (3.11.5.7.1)
H_p	=	ultimate bridge pier resistance (kip) (3.14.5.4)
H_s	=	ultimate bridge superstructure resistance (kip) (3.14.5.4)
HVE_i	=	the heavy vehicle base encroachment frequency (C3.6.5.1)
H_1	=	distance from ground surface to uppermost ground anchor (ft) (3.11.5.7.1)
h	=	notional height of earth pressure diagram (ft) (3.11.5.7.2)
h_{eq}	=	equivalent height of soil for vehicular load (ft) (3.11.6.4)
IM	=	dynamic load allowance (C3.6.1.2.5)
KE	=	design impact energy of vessel collision (kip-ft) (3.14.7)
K_1	=	ice force reduction factor for small streams (C3.9.2.3)
K_Z	=	pressure exposure and elevation coefficient (3.8.1.2.1)
k	=	coefficient of lateral earth pressure (3.11.5.1)
k_a	=	coefficient of active lateral earth pressure (3.11.5.3)
k_o	=	coefficient of at rest lateral earth pressure (3.11.5.2)
k_p	=	coefficient of passive lateral earth pressure (3.11.5.1)
k_s	=	coefficient of earth pressure due to surcharge (3.11.6.1)
L	=	perimeter of pier (ft); length of soil reinforcing elements in a mechanically stabilized earth (MSE) wall (ft); length of footing (ft); expansion length (in.) (3.9.5) (3.11.5.8.1) (3.11.6.3) (3.12.2.3)
$LLDF$	=	live load distribution factor as specified in Table 3.6.1.2.6-1a (3.6.1.2.6b)
L_s	=	horizontal length of sloping ground behind back face of retaining wall (ft) (3.11.5.8.1)
l_t	=	tire patch length, 10 (in.) (3.6.1.2.6b)
l_w	=	live load patch length at depth H (ft) (3.6.1.2.6b)
ℓ	=	characteristic length (ft); center-to-center spacing of vertical wall elements (ft) (C3.9.5) (3.11.5.6)
LOA	=	length overall of ship or barge tow including the tug or tow boat (ft) (3.14.5)
m	=	multiple presence factor; number of cohesionless soil layers in the top 100 ft (3.6.1.1.2) (3.10.3.1)
N	=	minimum support length (in.); number of one-way passages of vessels navigating through the bridge (number/yr) (C3.10.9.2) (3.14.5)
N_s	=	stability number (3.11.5.6)
OCR	=	overconsolidation ratio (3.11.5.2)
P	=	design wheel load (kip); live load applied at surface on all interacting wheels (kip); maximum vertical force for single ice wedge (kip); point load (kip); load resulting from vessel impact (kip); (C3.6.1.2.5) (3.6.1.2.6b) (C3.9.5) (C3.11.6.2) (3.14.5.4)
$P(C HVE_i)$	=	the probability of a collision given a heavy vehicle encroachment from (C3.6.5.1)
$P(Q_{CT} > R_{CPC})$	=	the probability of the worst-case collision force, Q_{CT} , exceeding the critical pier component capacity, R_{CPC} (C3.6.5.1)
PA	=	probability of vessel aberrancy (3.14.5)
P_a	=	force resultant per unit width of wall (kip/ft) (3.11.5.8.1)
P_B	=	barge collision impact force for head-on collision between barge bow and a rigid object (kip) (3.14.11)
$\overline{P_B}$	=	average equivalent static barge impact force resulting from Meir-Dornberg Study (kip) (C3.14.11)
P_{BH}	=	ship collision impact force between ship bow and a rigid superstructure (kip) (3.14.10.1)
PC	=	probability of bridge collapse (3.14.5)
P_{DH}	=	ship collision impact force between ship deck house and a rigid superstructure (kip) (3.14.5.4)
PG	=	geometric probability of vessel collision with bridge pier/span (3.14.5)
P_H	=	lateral force due to superstructure or other concentrated lateral loads (kip/ft) (3.11.6.3)
P_h	=	horizontal component of resultant earth pressure on wall (kip/ft) (3.11.5.5)
PI	=	plasticity index (ASTM D4318) (3.10.3.1)
P_i	=	offset to critical pier component in direction, I , in ft where the distance is from the face of the critical pier component to the closest edge of travel lane, i (C3.6.5.1)
P_L	=	live load vertical crown pressure (ksf) (3.6.1.2.6b)
P_{MT}	=	ship collision impact force between ship mast and a rigid superstructure (kip) (3.14.5.4)
P_p	=	passive earth pressure (kip/ft) (3.11.5.4)
P_S	=	ship collision impact force for head-on collision between ship bow and a rigid object (kip) (3.14.5.4)
P_v	=	vertical component of resultant earth pressure on wall (kip/ft); load per linear foot of strip footing (kip/ft) (3.11.5.5) (3.11.6.3)
P_Z	=	design wind pressure (ksf) (3.8.1.2.1)

P'_v	=	load on isolated rectangular footing or point load (kip) (3.11.6.3)
p	=	fraction of truck traffic in a single lane; pressure of flowing water (ksf); lateral earth pressure (psf); effective ice crushing strength (ksf); load intensity (ksf) (3.6.1.4.2) (3.7.3.1) (3.9.2.1) (3.11.5.1) (3.11.6.2)
p_a	=	<i>AEP</i> (ksf); maximum ordinate of pressure diagram (ksf) (3.11.5.3) (3.11.5.7.1)
p_p	=	passive lateral earth pressure (ksf) (3.11.5.4)
Q	=	total factored load; load intensity for infinitely long line loading (kip/ft) (3.4.1) (3.11.6.2)
Q_{CT}	=	worst-case collision force (kip) (C3.6.5.1)
Q_i	=	force effects (3.4.1)
q	=	surcharge pressure (ksf) (3.11.6.4)
q_s	=	uniform surcharge pressure (ksf) (3.11.6.1)
R	=	radius of curvature (ft); radius of circular pier (ft); seismic response modification factor; reduction factor of lateral passive earth pressure; reaction force to be resisted by subgrade below base of excavation (kip/ft); radial distance from point of load application to a point on the wall (ft) (3.6.3) (3.9.5) (3.10.7.1) (3.11.5.4) (3.11.5.7.1) (3.11.6.2)
R_B	=	<i>PA</i> correction factor for bridge location (3.14.5.2.3)
R_{BH}	=	ratio of exposed superstructure depth to the total ship bow depth (3.14.10.1)
R_C	=	<i>PA</i> correction factor for currents parallel to vessel transit path (3.14.5.2.3)
R_{CPC}	=	critical pier component capacity (C3.6.5.1)
R_D	=	<i>PA</i> correction factor for vessel traffic density (3.14.5.2.3)
R_{DH}	=	reduction factor for ship deck house collision force (3.14.10.2)
R_{XC}	=	<i>PA</i> correction factor for cross-currents acting perpendicular to vessel transit path (3.14.5.2.3)
r	=	radius of pier nose (ft) (C3.9.2.3)
S_a	=	design response spectral acceleration coefficient (3.10.4.1)
S_{D1}	=	equivalent 1.0 s acceleration coefficient (3.10.6)
S_f	=	freezing index (C3.9.2.2)
S_m	=	shear strength of rock mass (ksf) (3.11.5.6)
S_u	=	undrained shear strength of cohesive soil (ksf) (3.11.5.6)
S_{ub}	=	undrained strength of soil below excavation base (ksf) (3.11.5.7.2b)
s_a	=	axle spacing (ft) (3.6.1.2.6b)
s_w	=	wheel spacing, 6.0 ft (3.6.1.2.6b)
T	=	mean daily air temperature (degrees F) (C3.9.2.2)
T_F	=	period of fundamental mode of vibration of bridge (s) (3.10.2.2)
T_{hi}	=	horizontal load in anchor, <i>i</i> (kip/ft) (3.11.5.7.1)
T_{max}	=	applied load to reinforcement in a mechanically stabilized earth wall (kip/ft) (3.11.5.8.2)
$T_{MaxDesign}$	=	maximum design temperature used for thermal movement effects (degrees F) (3.12.2.1) (3.12.2.2) (3.12.2.3)
$T_{MinDesign}$	=	minimum design temperature used for thermal movement effects (degrees F) (3.12.2.1) (3.12.2.2) (3.12.2.3)
TR	=	horizontal curve toward fixed object (C3.6.5.1)
t	=	thickness of ice (ft); thickness of deck (in.) (3.9.2.2) (3.12.3)
V	=	design velocity of water (ft/s); design 3-second gust wind speed (mph); design impact speed of vessel (ft/s) (3.7.3.1) (3.8.1.1.2) (3.14.6)
V_C	=	waterway current component acting parallel to the vessel transit path (knots) (3.14.5.2.3)
V_{DZ}	=	design wind velocity at design Elevation <i>Z</i> (mph) (3.8.1.1)
V_{MIN}	=	minimum design impact velocity taken not less than the yearly mean current velocity for the bridge location (ft/s) (3.14.6)
V_T	=	vessel transit speed in the navigable channel (ft/s) (3.14.6)
V_{XC}	=	waterway current component acting perpendicular to the vessel transit path (knots) (3.14.5.2.3)
v	=	highway design speed (ft/s) (3.6.3)
$\bar{v}_s$	=	average shear wave velocity for the upper 100 ft of the soil profile (3.10.3.1)
W	=	displacement weight of vessel (tonne) (C3.14.5.1)
w	=	width of clear roadway (ft); width of pier at level of ice action (ft); specific weight of water (kcf); moisture content (ASTM D2216) (3.6.1.1.1) (C3.7.3.1) (3.9.2.2) (3.10.3.1)
w_t	=	tire patch width, 20 (in.) (3.6.1.2.6b)
w_w	=	live load patch width at depth <i>H</i> (ft) (3.6.1.2.6b)
X	=	horizontal distance from back of wall to point of load application (ft); distance to bridge element from the centerline of vessel transit path (ft) (3.11.6.2) (3.14.6)
X_c	=	distance to edge of channel from centerline of vessel transit path (ft) (3.14.6)
X_L	=	distance from centerline of vessel transit path equal to $3 \times LOA$ (ft) (3.14.6)
X_1	=	distance from the back of the wall to the start of the line load (ft) (3.11.6.2)

X_2	=	length of the line load (ft) (3.11.6.2)
Z	=	structure height above low ground or water level > 30 ft (ft); depth below surface of soil (ft); depth from the ground surface to a point on the wall under consideration (ft); vertical distance from point of load application to the elevation of a point on the wall under consideration (ft) (3.8.1.1) (3.11.6.2) (3.11.6.3)
Z_2	=	depth where effective width intersects back of wall face (ft) (3.11.6.3)
z	=	depth below surface of backfill (ft) (3.11.5.1)
α	=	coefficient for local ice condition; inclination of pier nose with respect to a vertical axis (degrees); inclination of back of wall with respect to a vertical axis (degrees); angle between foundation wall and a line connecting the point on the wall under consideration and a point on the bottom corner of the footing nearest to the wall (rad); coefficient of thermal expansion (in./in./degrees F) (3.9.2.2) (C3.9.2.2) (C3.11.5.3) (3.11.6.2) (3.12.2.3)
β	=	nose angle in a horizontal plane used to calculate transverse ice forces (degrees); slope of backfill surface behind retaining wall; {+ for slope up from wall; – for slope down from wall} (degrees) (3.9.2.4.1) (3.11.5.3)
β'	=	slope of ground surface in front of wall {+ for slope up from wall; – for slope down from wall} (degrees) (3.11.5.6)
γ	=	load factors; unit weight of water (kcf); unit weight of soil (kcf) (C3.4.1) (C3.6.1.2.5) (C3.9.5) (3.11.5.1)
γ_s	=	unit weight of soil (kcf) (3.11.5.1)
γ'_s	=	effective soil unit weight (kcf) (3.11.5.6)
γ_{DR}	=	load factor for drag load (3.4.1)
γ_{TU}	=	load factor for uniform temperature (3.4.1)
$\Delta\sigma_H$	=	horizontal stress due to surcharge load (ksf) (3.11.6.3)
$\Delta\sigma_v$	=	vertical stress due to surcharge load (ksf) (3.11.6.3)
δ	=	angle of truncated ice wedge (degrees); friction angle between fill and wall (degrees); angle between the far and near corners of a footing measured from the point on the wall under consideration (rad) (C3.9.5) (3.11.5.3) (3.11.6.2)
η_i	=	load modifier specified in Article 1.3.2; wall face batter (3.4.1) (3.11.5.9)
θ	=	angle of back of wall to the horizontal (degrees); angle of channel turn or bend (degrees); angle between direction of stream flow and the longitudinal axis of pier (degrees) (3.7.3.2) (3.11.5.3) (3.14.5.2.3)
θ_f	=	friction angle between ice floe and pier (degrees) (3.9.2.4.1)
σ	=	standard deviation of normal distribution (3.14.5.3)
σ_T	=	tensile strength of ice (ksf) (C3.9.5)
ν	=	Poisson's ratio (dim.) (3.11.6.2)
ϕ	=	resistance factors (C3.4.1)
ϕ_f	=	angle of internal friction (degrees) (C3.11.5.3) (3.11.5.4)
ϕ'_f	=	effective angle of internal friction (degrees) (3.11.5.2)
ϕ_p	=	soil friction angle for soil within passive resistance zone (degrees) (3.11.5.6)
ϕ_r	=	internal friction angle of reinforced fill (degrees) (3.11.6.3)
ϕ'_s	=	angle of internal friction of retained soil (degrees) (3.11.5.6)

3.3.2—Load and Load Designations

The following permanent and transient loads and forces shall be considered:

• Permanent Loads

CR	=	force effects due to creep
DR	=	drag load due to settlement of the adjacent ground
DC	=	dead load of structural components and nonstructural attachments
DW	=	dead load of wearing surfaces and utilities
EH	=	horizontal earth pressure load
EL	=	miscellaneous locked-in force effects resulting from the construction process, including jacking apart of cantilevers in segmental construction
ES	=	earth surcharge load

<i>EV</i>	=	vertical pressure from dead load of earth fill
<i>PS</i>	=	secondary forces from post-tensioning for strength limit states; total prestress forces for service limit states
<i>SH</i>	=	force effects due to shrinkage

- Transient Loads

<i>BL</i>	=	blast loading
<i>BR</i>	=	vehicular braking force
<i>CE</i>	=	vehicular centrifugal force
<i>CT</i>	=	vehicular collision force
<i>CV</i>	=	vessel collision force
<i>EQ</i>	=	earthquake load
<i>FR</i>	=	friction load
<i>IC</i>	=	ice load
<i>IM</i>	=	vehicular dynamic load allowance
<i>LL</i>	=	vehicular live load
<i>LS</i>	=	live load surcharge
<i>PL</i>	=	pedestrian live load
<i>SE</i>	=	force effect due to settlement
<i>TG</i>	=	force effect due to temperature gradient
<i>TU</i>	=	force effect due to uniform temperature
<i>WA</i>	=	water load and stream pressure
<i>WL</i>	=	wind on live load
<i>WS</i>	=	wind load on structure

3.4—LOAD FACTORS AND COMBINATIONS

3.4.1—Load Factors and Load Combinations

The total factored force effect, Q , shall be taken as:

$$Q = \sum \eta_i \gamma_i Q_i \quad (3.4.1-1)$$

where:

η_i	=	load modifier, specified in Article 1.3.2
Q_i	=	force effects from loads specified herein
γ_i	=	load factors, specified in Tables 3.4.1-1 to 3.4.1-6

Components and connections of a bridge shall satisfy Eq. 1.3.2.1-1 for the applicable combinations of factored extreme force effects as specified at each of the load combinations specified in Table 3.4.1-1 at the following limit states:

- Strength I—Basic load combination relating to the normal vehicular use of the bridge without wind.
- Strength II—Load combination relating to the use of the bridge by Owner-specified special design vehicles, evaluation permit vehicles, or both without wind.
- Strength III—Load combination relating to the bridge exposed to the design wind speed at the location of the bridge.

C3.4.1

The background for the load factors specified herein, and the resistance factors specified in other Sections of these Specifications is developed in Nowak (1992).

The permit vehicle should not be assumed to be the only vehicle on the bridge unless so assured by traffic control. See Article 4.6.2.2.5 regarding other traffic on the bridge simultaneously.

Vehicles become unstable at higher wind velocities. Therefore, high winds prevent the presence of significant live load on the bridge.

Wind load provisions in earlier editions of the specifications were based on fastest-mile wind speed measurements. The current wind load provisions are based

- Strength IV—Load combination emphasizing dead load force effects in bridge superstructures.

on 3-second wind gust speed with 7 percent probability of exceedance in 50 years (mean return period of 700 years).

The Strength IV load combination shown in these Specifications was not fully statistically calibrated. It does not include live load; it controls over Strength I for components with dead load to live load ratio exceeding 7.0. These are typically long span bridges. The reliability indices tend to increase with the increase in the dead load to live load ratio, albeit at slow rate for bridges with high ratios.

A study was performed by Modjeski and Masters, Inc. (Wassef et al., 2014) using the same process to calibrate Strength IV as was used to statistically calibrate the Strength I load combination. Some load combinations that still emphasized dead load force effects, but produced a more uniform reliability across the possible practical range of dead load to live load ratios, were proposed. However, except for steel trusses, the relative effect on the controlling factored design loads was small and did not warrant changing the current load combination. Trusses and other structures with high *DL/LL* ratios can come closer to the targeted reliability of 3.5 by using the equation $1.4DC + 1.5DW + 1.45LL$. Trusses see the largest increase in the reliability index. However, the true reliability of steel trusses, steel box girders, and concrete box girder structures may be higher than reported in this study due to:

- not having been included in the live load distribution factor study that refined the design load for more common bridge types.
- the HL-93 loading being conservative for long-span bridges, as discussed in Article C3.6.1.3.

This load combination is not applicable to investigation of construction stages, substructures, earth retaining systems, and bearing design.

When applied with the load factor specified in Table 3.4.1-1 (i.e., 1.0), the 80 mph 3-second gust wind speed is approximately equivalent to the 100 mph fastest-mile wind used in earlier specifications applied with a load factor of 0.4. The latter was meant to be equivalent to a 55 mph fastest-mile wind applied with a load factor of 1.4.

Past editions of the Standard Specifications used $\gamma_{EQ} = 0.0$. This issue is not resolved. The possibility of partial live load, i.e., $\gamma_{EQ} < 1.0$, with earthquakes should be considered. Application of Turkstra's rule for combining uncorrelated loads indicates that $\gamma_{EQ} = 0.50$ is reasonable for a wide range of values of average daily truck traffic (*ADTT*).

The following applies to both Extreme Event I and II:

- The design objective is life safety, i.e., noncollapse of the structure. Inelastic behavior such as spalling of concrete and bending of steel members is expected. In most cases the risk does not warrant the expense of designing for elastic behavior so long as vertical-load-carrying capacity is maintained for service-level loads.

- Strength V—Load combination relating to normal vehicular use of the bridge with wind of 80 mph velocity.
- Extreme Event I—Load combination including earthquake. The load factor for live load, γ_{EQ} , shall be determined on a project-specific basis.
- Extreme Event II—Load combination relating to ice load, blast load, collision by vessels and vehicles, and check floods.

Where deck overhang design or substructure components are investigated for vehicular collision load, *CT*, use the minimum value for *LL+IM* and the maximum value for *CT*.

Where a pier may be exposed to a collision load but is not designed explicitly for the *CT* loading, investigate with one column missing for post-collision evaluation using the maximum value for *LL+IM* and no *CT* loading.

- Service I—Load combination relating to the normal operational use of the bridge with a 70 mph wind and all loads taken at their nominal values. Also related to deflection control in buried metal structures, tunnel liner plate, and thermoplastic pipe, to control crack width in reinforced concrete structures, and for transverse analysis relating to tension in concrete segmental girders.
- Service II—Load combination intended to control yielding of steel structures and slip of slip-critical connections due to vehicular live load. For structures with unique truck loading conditions, such as access roads to ports or industrial sites which might lead to a disproportionate number of permit loads, a site-specific increase in the load factor should be considered.
- Service III—Load combination for longitudinal analysis relating to flexural tension, and principal tension in the webs of prestressed concrete superstructures with the objective of crack control.
- Prior to 2015, these Specifications used a value for γ_p greater than 1.0. This practice went against the intended philosophy behind the extreme event limit state. A more conservative design is attained by increasing the hazard and using ductile detailing, rather than increasing γ_p , i.e., force effects due to permanent loads.
- The recurrence interval of extreme events is thought to exceed the design life.
- Although these limit states include water loads, *WA*, the effects due to *WA* are considerably less significant than the effects of changes to foundation condition due to scour. Article 2.6.4.4 addresses the effects of scour combined with extreme event limit states.
- The joint probability of *BL*, *EQ*, *CT*, *CV*, and *IC* is extremely low, and, therefore, the events are specified to be applied separately. Under these extreme conditions, the structure may undergo considerable inelastic deformation by which locked-in force effects due to *TU*, *TG*, *CR*, *SH*, and *SE* are expected to be relieved.

The 0.50 live load factor signifies a low probability of the concurrence of the maximum vehicular live load (other than *CT*) and the extreme events.

Compression in prestressed concrete components and tension in prestressed bent caps are investigated using this load combination. Service III is used to investigate tensile stresses in prestressed concrete components.

When applied with the load factor specified in Table 3.4.1-1 (i.e., 1.0), the 70 mph 3-second gust wind speed is equivalent to the 100 mph fastest-mile wind used in earlier specifications applied with a load factor of 0.3. The latter was meant to be equivalent to a 55-mph fastest-mile wind applied with a load factor of 1.0.

This load combination corresponds to the overload provision for steel structures in past editions of the *AASHTO Standard Specifications for Highway Bridges*, and it is applicable only to steel structures. From the point of view of load level, this combination is approximately halfway between that used for Service I and Strength I Limit States. An evaluation of WIM data from 31 sites around the country (Kulicki et al., 2015) indicated that the probability of exceeding the load level specified in Table 3.4.1-1 for this limit state could be less than once every six months.

Prior to 2014, the longitudinal analysis relating to tension in prestressed concrete superstructures was investigated using a load factor for live load of 0.8. This load factor reflects, among other things, current exclusion weight limits mandated by various jurisdictions at the time of the development of the specifications in 1993. Vehicles permitted under these limits have been in service for many years prior to 1993. It was concluded at that time that, for longitudinal loading, there is no nationwide physical evidence that these vehicles have caused cracking in existing prestressed concrete components. The 0.8 load factor was applied regardless of the method used for determining the loss of prestressing.

- Service IV—Load combination relating only to tension in prestressed concrete columns with the objective of crack control.

The calibration of the service limit states for concrete components (Wassef et al., 2014) concluded that typical components designed using the Refined Estimates of Time-dependent Losses method incorporated in the Specifications in 2005, which includes the use of transformed sections and elastic gains, have a lower reliability index against flexural cracking in prestressed components than components designed using the prestress loss calculation method specified prior to 2005 based on gross sections and do not include elastic gains. For components designed using the currently-specified methods for instantaneous prestressing losses and the currently-specified Refined Estimates of Time-dependent Losses method, an increase in the load factor for live load from 0.8 to 1.0 was required to maintain the level of reliability against cracking of prestressed concrete components inherent in the system.

Service I should be used for checking tension related to transverse analysis of concrete segmental girders.

Wind load for Service IV load combination in earlier specifications was based on fastest-mile wind of 100 mph applied with a load factor of 0.7. This load represents an 84-mph fastest-mile wind applied with a load factor of 1.0. This wind load was meant to result in zero tension in prestressed concrete columns for ten-year mean reoccurrence winds. The wind speed specified in Table 3.8.1.1.2-1 for Service IV limit state is a product of the following:

- The wind speed used for the Strength III load combination taken as the 3-second gust wind speed with 7 percent probability of exceedance in 50 years.
- The ratio of the 3-second gust wind speed with 7 percent probability of exceedance in 10 years and 50 years, approximately 87 percent,
- A reduction factor equal to the square root of $1/1.4$ or 0.845 . This reduction factor is meant to reduce the resulting wind pressure by $1/1.4$, the traditional ratio between wind pressures used for the strength limit states and service limit states for the same wind speed.

The prestressed concrete columns must still meet strength requirements as set forth in Load Combination Strength III in Article 3.4.1.

It is not recommended that thermal gradient be combined with high wind forces. Superstructure expansion forces are included.

- **Fatigue I**—Fatigue and fracture load combination related to infinite load-induced fatigue life.

The load factor for the Fatigue I load combination, applied to a single design truck having the axle spacing specified in Article 3.6.1.4.1, reflects load levels found to be representative of the maximum stress range of the truck population for infinite fatigue life design. In previous editions of the AASHTO *LRFD Bridge Design Specifications*, the load factor for this load combination was chosen on the assumption that the maximum stress range in the random variable spectrum is twice the effective stress range caused by the Fatigue II load combination. A reassessment of fatigue live load reported in Kulicki et al. (2015) indicated that the load factors for

- Fatigue II—Fatigue and fracture load combination related to finite load-induced fatigue life.

The load factors for various loads comprising a design load combination shall be taken as specified in Table 3.4.1-1. All relevant subsets of the load combinations shall be investigated. For each load combination, every load that is indicated to be taken into account and that is germane to the component being designed, including all significant effects due to distortion, shall be multiplied by the appropriate load factor and multiple presence factor specified in Article 3.6.1.1.2, if applicable. The products shall be summed as specified in Eq. 1.3.2.1-1 and multiplied by the load modifiers specified in Article 1.3.2.

The factors shall be selected to produce the total extreme factored force effect. For each load combination, both positive and negative extremes shall be investigated.

In load combinations where one force effect decreases another effect, the minimum value shall be applied to the load reducing the force effect. For permanent force effects, the load factor that produces the more critical combination shall be selected from Table 3.4.1-2. Where the permanent load increases the stability or load-carrying capacity of a component or bridge, the minimum value of the load factor for that permanent load shall also be investigated.

Fatigue I and Fatigue II should be upgraded to the values now shown in Table 3.4.1-1 to reflect current truck traffic. The resulting ratio between the load factor for the two fatigue load combinations is 2.2.

The load factor for the Fatigue II load combination, applied to a single design truck, reflects a load level found to be representative of the effective stress range of the truck population with respect to a small number of stress range cycles and to their cumulative effects in steel elements, components, and connections for finite fatigue life design.

This Article reinforces the traditional method of selecting load combinations to obtain realistic extreme effects and is intended to clarify the issue of the variability of permanent loads and their effects. As has always been the case, the Owner or Designer may determine that not all of the loads in a given load combination apply to the situation under investigation.

It is recognized herein that the actual magnitude of permanent loads may also be less than the nominal value. This becomes important where the permanent load reduces the effects of transient loads.

It has been observed that permanent loads are more likely to be greater than the nominal value than to be less than this value.

The earth load factor for thermoplastic culverts is set to 1.3; however, to preserve the overall safety at the same levels as historical specifications, an earth-load-installation factor is introduced later in these Specifications as part of the implementation of NCHRP Report 631. This factor may be adjusted based on field control of construction practices.

In the application of permanent loads, force effects for each of the specified six load types should be computed separately. It is unnecessary to assume that one type of load varies by span, length, or component within a bridge. For example, when investigating uplift at a bearing in a continuous beam, it would not be appropriate to use the maximum load factor for permanent loads in spans that produce a negative reaction and the minimum load factor in spans that produce a positive reaction. Consider the investigation of uplift. Uplift, which was treated as a separate load case in past editions of the *AASHTO Standard Specifications for Highway Bridges*, now becomes a strength load combination. Where a permanent load produces uplift, that load would be multiplied by the maximum load factor, regardless of the span in which it is located. If another permanent load reduces the uplift, it would be multiplied by the minimum load factor, regardless of the span in which it is located. For example, at Strength I Limit State where the permanent load reaction is positive and live load can cause a negative reaction, the load combination would be $0.9DC + 0.65DW + 1.75(LL + IM)$. If both reactions were negative, the load combination would be $1.25DC + 1.50DW + 1.75(LL + IM)$. For each force effect, both extreme combinations may need to be investigated by applying either the high or the

The evaluation of overall stability of retained fills, as well as earth slopes with or without a shallow or deep foundation unit, should be investigated at the strength and extreme event limit states based on the Strength I and Extreme Event I load combinations using γ_p for overall stability as specified in Table 3.4.1-2 and an appropriate resistance factor as specified in Article 11.6.3.7. If the externally applied load(s) contribute to the stability of the slope, the externally applied load should not be included in the load combination used for design of the slope. However, if the foundation element is designed to resist the additional load induced on the element by the slope instability, design of the slope for overall stability may include the resisting load applied to the slope by the foundation element.

The evaluation of foundation movements as defined in Article 10.5.2.2 shall be conducted in accordance with Article 10.6.2.4 using the load factor, γ_{SE} , specified in Table 3.4.1-5.

For structural plate box structures complying with the provisions of Article 12.9, the live load factor for the vehicular live loads, *LL* and *IM*, shall be taken as 2.0.

low load factor as appropriate. The algebraic sums of these products are the total force effects for which the bridge and its components should be designed.

PS, *CR*, *SH*, *TU*, and *TG* are superimposed deformations as defined in Article 3.12. For prestressed members in typical bridge types, secondary prestressing, creep, and shrinkage are generally designed for in the service limit state. In concrete segmental structures, *CR* and *SH* are factored by γ_p for *DC* because analysis for time-dependent effects in segmental bridges is nonlinear. Abutments, piers, columns, and bent caps are to be considered as substructure components.

Because force effects due to uniform temperature change, temperature gradient, prestressing, creep, and shrinkage are the result of imposed deformation, member and foundation stiffness can have a significant impact on calculated values. Pursuant to Articles 4.5.1 and 4.5.2, and for certain limit states, consideration may be given to the effects of cracking on the stiffness of concrete members placed in flexure as well as the flexibility of foundation systems.

The calculation of displacements for *TU* utilizes a factor greater than 1.0 to avoid undersizing joints, expansion devices, and bearings.

Loads on foundations due to forces caused by slope instability should be determined in accordance with Liang (2010), or Vessely et al. (2007) and Yamasaki et al. (2013). Illustrations of this are provided in Figures C3.4.1-1 and C3.4.1-2.

Available slope stability design procedures and programs produce a single factor of safety, *FS*, using limit equilibrium. However, because the specific location of the critical failure surface varies depending on the overall slope geometry, subsurface stratigraphy, and external loads acting on the failure mass, and since a portion of the gravity force acting on the failure mass contributes to load and a portion contributes to resistance, there is no effective way to apply a load factor directly to the loads within the soil failure mass. Hence, the load factor of 1.0 for overall stability in Table 3.4.1-2 is combined with a resistance factor that is equal to $1/FS$ as provided in Article 10.5.5.2.1 and Article 11.6.3.7. Furthermore, slope stability analysis uses limit equilibrium concepts rather than slope deformation to assess shear failure of the soil. Therefore, overall stability is conducted for strength and extreme event limit states.

If reinforcement elements are placed through the slope failure mass to improve its stability, they should be considered to be resisting elements. Appropriate resistance factors should be applied to the resistance derived from those elements. For foundations, resistance factors that should be used are as specified in Article 10.5.5.2. For soil reinforcement elements such as are normally associated with walls, resistance factors that should be used are as specified in Article 11.5.7.

Figure C3.4.1-1—Examples Illustrating the Concept of Overall Stability as Applied to the Situation when a Slope Supports a Structural Element

Figure C3.4.1-2—Examples Illustrating when Foundation Elements Contribute to Instability or to Stability of the Slope

Applying these criteria for the evaluation of the sliding resistance of walls:

- The vertical earth load on the rear of a cantilevered retaining wall would be multiplied by γ_{pmin} (1.00) and the weight of the structure would be multiplied by γ_{pmin} (0.90) because these forces result in an increase in the contact stress (and shear strength) at the base of the wall and foundation.
- The horizontal earth load on a cantilevered retaining wall would be multiplied by γ_{pmax} (1.50) for an active earth pressure distribution because the force results in a more critical sliding force at the base of the wall.

Similarly, the values of γ_{pmax} for structure weight (1.25), vertical earth load (1.35) and horizontal active earth pressure (1.50) would represent the critical load combination for an evaluation of foundation bearing resistance.

Water load and friction are included in all strength load combinations at their respective nominal values.

For creep and shrinkage, the specified nominal values should be used. For friction, settlement, and water loads, both minimum and maximum values need to be investigated to produce extreme load combinations.

The load factor for temperature gradient should be determined on the basis of the:

- Type of structure, and

The load factor for temperature gradient, γ_{TG} , should be considered on a project-specific basis. In lieu of project-specific information to the contrary, γ_{TG} may be taken as:

- 0.0 at the strength and extreme event limit states,
- 1.0 at the service limit state when live load is not considered, and
- 0.50 at the service limit state when live load is considered.

- Limit state being investigated.

Open girder construction and multiple steel box girders have traditionally, but perhaps not necessarily correctly, been designed without consideration of temperature gradient, i.e., $\gamma_{TG} = 0.0$.

The load factors specified for mechanically stabilized earth (MSE) wall internal stability are applicable to loads imparted to the soil reinforcement by vertical gravity forces from the soil backfill and surcharge. Since soil reinforcement always contributes to wall stability, no minimum load factors are specified. The magnitude of these load factors depend on the design method selected, as these load factors have been calibrated from measured data using reliability theory calibration procedures (Allen et al., 2005) (Allen and Bathurst, 2018). The load factors for MSE wall internal stability are applicable to the Strength limit state except where specifically noted (i.e., soil failure for the Stiffness Method in Table 3.4.1-2).

The values for γ_{SE} provided in Table 3.4.1-5 are based on Samtani and Allen (2018).

For bridges in which estimated foundation total settlements are small, past typical design practice has been to not explicitly consider γ_{SE} and the factored force effect due to differential settlement, as based on long-term experience, that force effect is not likely to be a controlling factor in the design. This “legacy” design approach may be used if the geomaterials at a site are well understood, and past experience has shown that for the considered foundation and service bearing pressure, structural or geometric consequences are likely to be minor.

An Owner may choose to use a local method that provides better estimation of foundation movements for local geologic conditions compared to the methods specified in Table 3.4.1-5. In such cases, the owner will need to calibrate the γ_{SE} value for the local method using the procedures described in Kulicki, et al. (2015), Samtani and Kulicki (2018) and Samtani and Allen (2018).

The value of $\gamma_{SE}=1.00$ for consolidation (time-dependent long-term) settlement assumes that the estimation of consolidation settlement is based on appropriate laboratory and field tests to determine parameters (rather than correlations with index properties of soils) in the consolidation settlement equations in Article 10.6.2.4.3.

The effects of the foundation movements on the bridge superstructure, retaining walls, or other load bearing structures shall be evaluated at applicable strength and service limit states using the provisions of Article 10.5.2.2 and the load factor, γ_{SE} , specified in Table 3.4.1-5. For all bridges, stiffness should be appropriate to the considered limit state. Similarly, the effects of continuity with the substructure should be considered. In assessing the structural implications of foundation movements of concrete bridges, the determination of the stiffness of the bridge components should consider the effects of cracking, creep, and other inelastic responses.

Load combinations which include settlement shall also be applied without settlement. As specified in Article 3.12.6, differential movements between and within substructure units shall be considered when determining the most critical combinations of force effects.

Downdrag shall be evaluated at the service limit state using the provisions of Article 3.11.8.

For segmentally constructed bridges, the following combination shall be investigated at the service limit state:

$$DC + DW + EH + EV + ES + WA + CR + SH + TG + EL + PS \quad (3.4.1-2)$$

Table 3.4.1-1—Load Combinations and Load Factors

Load Combination Limit State	DC DW EH EV ES EL PS CR SH	LL IM CE BR PL LS	WA	WS	WL	FR	TU	TG	SE	DR	Use One of These at a Time				
											EQ	BL	IC	CT	CV
Strength I (unless noted)	γ_P	1.75	1.00	—	—	1.00	γ_{TU}	γ_{TG}	γ_{SE}	γ_{DR}	—	—	—	—	—
Strength II	γ_P	1.35	1.00	—	—	1.00	γ_{TU}	γ_{TG}	γ_{SE}	γ_{DR}	—	—	—	—	—
Strength III	γ_P	—	1.00	1.00	—	1.00	γ_{TU}	γ_{TG}	γ_{SE}	γ_{DR}	—	—	—	—	—
Strength IV	γ_P	—	1.00	—	—	1.00	γ_{TU}	—	—	—	—	—	—	—	—
Strength V	γ_P	1.35	1.00	1.00	1.00	1.00	γ_{TU}	γ_{TG}	γ_{SE}	γ_{DR}	—	—	—	—	—
Extreme Event I	1.00	γ_{EQ}	1.00	—	—	1.00	—	—	—	1.00	1.00	—	—	—	—
Extreme Event II	1.00	0.5/1.00	1.00	—	—	1.00	—	—	—	1.00	—	1.00	1.00	1.00/	1.00

Service II	1.00	1.30	1.00	—	—	1.00	γ_{TU}	—	—	—	—	—	—	—	—
Service III	1.00	γ_{LL}	1.00	—	—	1.00	γ_{TU}	γ_{TG}	γ_{SE}	1.00	—	—	—	—	—
Service IV	1.00	—	1.00	1.00	—	1.00	γ_{TU}	—	1.00	1.00	—	—	—	—	—
Fatigue I— LL , IM & CE only	—	1.75	—	—	—	—	—	—	—	—	—	—	—	—	—
Fatigue II— LL , IM & CE only	—	0.80	—	—	—	—	—	—	—	—	—	—	—	—	—

Notes: For Service I, the load factor for EV equals 1.2 for Stiffness Method Soil Failure as shown in Table 3.4.1-2.
The value of γ_P shall be taken from Tables 3.4.1-2 and 3.4.1-3.
The value of γ_{LL} shall be taken from Table 3.4.1-4.
The value of γ_{SE} shall be taken from Table 3.4.1-5.
The value of γ_{TU} shall be taken from Table 3.4.1-6.
For Structural Strength, the load factor for DR , γ_{DR} , equals 1.10 and for Geotechnical Strength, γ_{DR} equals 0.00.

factors for the weight of the structure and appurtenances, *DC* and *DW*, shall not be less than 1.25.

Unless otherwise specified by the Owner, construction loads including dynamic effects (if applicable) shall be added in Strength Load Combination I with a load factor not less than 1.5 when investigating for maximum force effects.

The load factor for wind during construction in Strength Load Combination III shall be as specified by the Owner. Any applicable construction loads shall be included with a load factor not less than 1.25.

Unless otherwise specified by the Owner, primary steel superstructure components shall be investigated for maximum force effects during construction for an additional load combination consisting of the applicable *DC* loads and any construction loads that are applied to the fully erected steelwork. For this additional load combination, the load factor for *DC* and construction loads including dynamic effects (if applicable) shall not be less than 1.4.

3.4.2.2—Evaluation of Deflection at the Service Limit State

In the absence of special provisions to the contrary, where evaluation of construction deflections are required by the contract documents, Service Load Combination I shall apply. Except for segmentally constructed bridges, construction loads shall be added to the Service Load Combination I, with a load factor of 1.00. Appropriate load combinations and allowable stresses for segmental bridges are addressed in Article 5.12.5.3. The associated permitted deflections shall be included in the contract documents.

3.4.3—Load Factors for Jacking and Post-Tensioning Forces

3.4.3.1—Jacking Forces

Unless otherwise specified by the Owner, the design forces for jacking in service shall not be less than 1.3 times the permanent load reaction at the bearing, adjacent to the point of jacking.

Where the bridge will not be closed to traffic during the jacking operation, the jacking load shall also contain a live load reaction consistent with the maintenance of traffic plan, multiplied by the load factor for live load.

3.4.3.2—Force for Post-Tensioning Anchorage Zones

The design force for post-tensioning anchorage zones shall be taken as 1.2 times the maximum jacking force.

not accurately known at the time of design. Construction loads include but are not limited to the weight of materials, removable forms, personnel, and equipment such as deck finishing machines or loads applied to the structure through falsework or other temporary supports. The Owner may consider noting the construction loads assumed in the design on the contract documents. The weight of the wet concrete deck and any stay-in-place forms should be considered as *DC* loads.

For steel superstructures, the use of higher-strength steels, composite construction, and limit-states design approaches in which smaller factors are applied to dead load force effects than in previous service-load design approaches have generally resulted in lighter members overall.

To ensure adequate stability and strength of primary steel superstructure components during construction, an additional strength limit state load combination is specified for the investigation of loads applied to the fully erected steelwork.

3.4.4—Load Factors for Orthotropic Decks at the Fatigue Limit State

The Fatigue I live load factor, γ_{LL} , shall be multiplied by an additional factor of 1.3 when evaluating fatigue at the welded rib-to-floorbeam cut-out detail and the rib-to-deck weld.

C3.4.4

Evaluation of the maximum stress range in the rib-to-deck weld as well as in the vicinity of the cut-out for this type of detail has demonstrated that the use of a 1.75 load factor for LL is unconservative. For the rib-to-deck weld and when a cut-out is used to relieve the secondary stresses imparted by the rotation of the rib relative to the floorbeam, the appropriate γ_{LL} should be increased to 2.25 (Connor, 2002). The increased Fatigue I load factor is based on stress range spectra monitoring of orthotropic decks. Studies indicate that the ratio of maximum stress range to effective stress range is increased as compared to standard bridge girders. This is due to a number of factors such as occasional heavy wheels and reduced local load distribution that occurs in deck elements. These Specifications produce a ratio that is consistent with the original findings of NCHRP Report 299 (Moses et al., 1987).

Earlier editions of these Specifications used an additional factor of 1.5 that was applied to the then-current 1.5 load factor for Fatigue I resulting in an effective load factor of 2.25. The current additional factor of 1.3 results in essentially the same combined load factor when applied to the current load factor of 1.75 for Fatigue I.

3.4.5—Load Factors for Cross-Frames and Diaphragms at the Fatigue Limit State

The Fatigue I and II live load factors, γ_{LL} , shall be multiplied by an additional factor of 0.65 when evaluating load-induced fatigue in cross-frames and diaphragms.

C3.4.5

Evaluation of the maximum and effective stress ranges in cross-frame members of steel I-girder systems has demonstrated that the respective use of 1.75 and 0.80 load factors for Fatigue I and II is overly conservative. The reduced load factors, which are based on weigh-in-motion data and analytical evaluation of cross-frames, is largely attributed to the sensitivity of transverse load position on cross-frame force response (NCHRP, 2021). The statistical calibration and resulting reliability indices of the updated load factors are consistent with the procedures and criteria utilized in Kulicki et al. (2015). This reduced load factor is independent of the analysis procedures outlined in Article 4.6.3.3.4 that are often used to estimate live load forces in cross-frames and diaphragms.

3.5—PERMANENT LOADS

3.5.1—Dead Loads: DC , DW , and EV

Dead loads shall include the weight of all components of the structure, appurtenances and utilities attached thereto, earth cover, wearing surface, future overlays, and planned widenings.

In the absence of more precise information, the unit weights, specified in Table 3.5.1-1, may be used for dead loads.

C3.5.1

Table 3.5.1-1 provides traditional unit weights. The unit weight of granular materials depends upon the degree of compaction and water content. The unit weight of concrete is primarily affected by the unit weight of the aggregate, which varies by geographical location and increases with concrete compressive strength. The unit weight of reinforced concrete is generally taken as

0.005 kcf greater than the unit weight of plain concrete. The values provided for wood include the weight of mandatory preservatives. The weight of transit rails, etc., is to be used only for preliminary design.

Table 3.5.1-1—Unit Weights

Material		Unit Weight (kcf)
Aluminum Alloys		0.175
Bituminous Wearing Surfaces		0.140
Cast Iron		0.450
Cinder Filling		0.060
Compacted Sand, Silt, or Clay		0.120
Concrete	Lightweight	0.110 to 0.135
	Normal Weight with $f'_c \leq 5.0$ ksi	0.145
	Normal Weight with $5.0 < f'_c \leq 15.0$ ksi	$0.140 + 0.001 f'_c$
Loose Sand, Silt, or Gravel		0.100
Soft Clay		0.100
Rolled Gravel, Macadam, or Ballast		0.140
Steel		0.490
Stone Masonry		0.170
Wood	Hard	0.060
	Soft	0.050
Water	Fresh	0.0624
	Salt	0.0640
Item		Weight per Unit Length (klf)
Transit Rails, Ties, and Fastening per Track		0.200

3.5.2—Earth Loads: *EH*, *ES*, and *DR*

Earth pressure, earth surcharge, and drag loads shall be as specified in Article 3.11.

3.6—LIVE LOADS

3.6.1—Gravity Loads: *LL* and *PL*

3.6.1.1—Vehicular Live Load

3.6.1.1.1—Number of Design Lanes

C3.6.1.1.1

Unless specified otherwise, the width of the design lanes should be taken as 12.0 ft. The number of design lanes should be determined by taking the integer part of the ratio $w/12.0$, where w is the clear roadway width in feet between curbs, barriers, or both. Possible future changes in the physical or functional clear roadway width of the bridge should be considered.

In cases where the traffic lanes are less than 12.0 ft wide, the number of design lanes shall be equal to the number of traffic lanes, and the width of the design lane shall be taken as the width of the traffic lane.

Roadway widths from 20.0 to 24.0 ft shall have two design lanes, each equal to one-half the roadway width.

It is not the intention of this Article to promote bridges with narrow traffic lanes. Wherever possible, bridges should be built to accommodate the standard design lane and appropriate shoulders.

3.6.1.1.2—Multiple Presence of Live Load

The provisions of this Article shall not be applied to the fatigue limit state for which one design truck is used, regardless of the number of design lanes. Where the single-lane approximate distribution factors in Articles 4.6.2.2 and 4.6.2.3 are used, other than the lever rule and static method, the force effects shall be divided by 1.20.

Unless specified otherwise herein, the extreme live load force effect shall be determined by considering each possible combination of number of loaded lanes multiplied by a corresponding multiple presence factor to account for the probability of simultaneous lane occupation by the full HL-93 design live load. In lieu of site-specific data, the values in Table 3.6.1.1.2-1:

- shall be used when investigating the effect of one lane loaded, and
- may be used when investigating the effect of three or more lanes loaded.

For the purpose of determining the number of lanes when the loading condition includes the pedestrian loads specified in Article 3.6.1.6 combined with one or more lanes of the vehicular live load, the pedestrian loads may be taken to be one loaded lane.

The factors specified in Table 3.6.1.1.2-1 shall not be applied in conjunction with approximate load distribution factors specified in Articles 4.6.2.2 and 4.6.2.3, except where the lever rule is used or where special requirements for exterior beams in beam-slab bridges, specified in Article 4.6.2.2.2d, are used.

Table 3.6.1.1.2-1—Multiple Presence Factors, m

Number of Loaded Lanes	Multiple Presence Factors, m
1	1.20
2	1.00
3	0.85
>3	0.65

C3.6.1.1.2

The multiple presence factors have been included in the approximate equations for distribution factors in Articles 4.6.2.2 and 4.6.2.3, both for single and multiple lanes loaded. The equations are based on evaluation of several combinations of loaded lanes with their appropriate multiple presence factors and are intended to account for the worst-case scenario. Where use of the lever rule is specified in Article 4.6.2.2 and 4.6.2.3, the Engineer must determine the number and location of vehicles and lanes, and, therefore, must include the multiple presence. Stated another way, if a sketch is required to determine load distribution, the Engineer is responsible for including multiple presence factors and selecting the worst design case. The factor, 1.20, from Table 3.6.1.1.2-1, has already been included in the approximate equations and should be removed for the purpose of fatigue investigations.

The entry greater than 1.0 in Table 3.6.1.1.2-1 results from statistical calibration of these Specifications on the basis of pairs of vehicles instead of a single vehicle. Therefore, when a single vehicle is on the bridge, it can be heavier than each one of a pair of vehicles and still have the same probability of occurrence.

The consideration of pedestrian loads counting as a “loaded lane” for the purpose of determining a multiple presence factor, m , is based on the assumption that simultaneous occupancy by a dense loading of people combined with a 75-year design live load is remote. For the purpose of this provision, it has been assumed that if a bridge is used as a viewing stand for eight hours each year for a total time of about one month, the appropriate live load to combine with it would have a one-month recurrence interval. This is reasonably approximated by use of the multiple presence factors, even though they are originally developed for vehicular live load.

Thus, if a component supported a sidewalk and one lane, it would be investigated for the vehicular live load alone with $m = 1.20$, and for the pedestrian loads combined with the vehicular live load with $m = 1.0$. If a component supported a sidewalk and two lanes of vehicular live load, it would be investigated for:

- one lane of vehicular live load, $m = 1.20$;
- the greater of the more significant lanes of vehicular live load and the pedestrian loads or two lanes of vehicular live load, $m = 1.0$, applied to the governing case; and
- two lanes of vehicular live load and the pedestrian loads, $m = 0.85$.

The multiple presence factor of 1.20 for a single lane does not apply to the pedestrian loads. Therefore, the case of the pedestrian loads without the vehicular live load is a subset of the second bulleted item.

The multiple presence factors in Table 3.6.1.1.2-1 were developed on the basis of an *ADTT* of 5,000 trucks in one direction. The force effect resulting from the appropriate number of lanes may be reduced for sites with lower *ADTT* as follows:

- If $100 \leq ADTT \leq 1,000$, 95 percent of the specified force effect may be used; and
- If $ADTT < 100$, 90 percent of the specified force effect may be used.

This adjustment is based on the reduced probability of attaining the design event during a 75-year design life with reduced truck volume.

3.6.1.2—Design Vehicular Live Load

3.6.1.2.1—General

Vehicular live loading on the roadways of bridges or incidental structures, designated HL-93, shall consist of a combination of the:

- Design truck or design tandem, and
- Design lane load.

Except as modified in Article 3.6.1.3.1, each design lane under consideration shall be occupied by either the design truck or tandem, coincident with the lane load, where applicable. The loads shall be assumed to occupy 10.0 ft transversely within a design lane.

C3.6.1.2.1

Consideration should be given to site-specific modifications to the design truck, design tandem, and/or the design lane load under the following conditions:

- The legal load of a given jurisdiction is significantly greater than typical;
- The roadway is expected to carry unusually high percentages of truck traffic;
- Flow control, such as a stop sign, traffic signal, or toll booth, causes trucks to collect on certain areas of a bridge or to not be interrupted by light traffic; or
- Special industrial loads are common due to the location of the bridge.

See also discussion in Article C3.6.1.3.1.

The live load model, consisting of either a truck or tandem coincident with a uniformly distributed load, was developed as a notional representation of shear and moment produced by a group of vehicles routinely permitted on highways of various states under “grandfather” exclusions to weight laws. The vehicles considered to be representative of these exclusions were based on a study conducted by the Transportation Research Board (Cohen, 1990). The load model is called “notional” because it is not intended to represent any particular truck.

In the initial development of the notional live load model, no attempt was made to relate to escorted permit loads, illegal overloads, or short duration special permits. The moment and shear effects were subsequently compared to the results of truck weight studies (Csagoly and Knobel, 1981) (Nowak, 1992) (Kulicki and Mertz, 2006), selected Weigh-in-Motion (WIM) data, and the 1991 Ontario Highway Bridge Design Code (OHBDC) live load model. These subsequent comparisons showed that the notional load could be scaled by appropriate load factors to be representative of these other load spectra.

Earlier editions of the commentary included information about the background of the HL-93. This information can be found in Kulicki (2006).

3.6.1.2.2—Design Truck

The weights and spacings of axles and wheels for the design truck shall be as specified in Figure 3.6.1.2.2-1. A dynamic load allowance shall be considered as specified in Article 3.6.2.

Except as specified in Articles 3.6.1.3.1 and 3.6.1.4.1, the spacing between the two 32.0-kip axles shall be varied between 14.0 ft and 30.0 ft to produce extreme force effects.

Figure 3.6.1.2.2-1—Characteristics of the Design Truck

3.6.1.2.3—Design Tandem

The design tandem shall consist of a pair of 25.0-kip axles spaced 4.0 ft apart. The transverse spacing of wheels shall be taken as 6.0 ft. A dynamic load allowance shall be considered as specified in Article 3.6.2.

3.6.1.2.4—Design Lane Load

The design lane load shall consist of a load of 0.64 klf uniformly distributed in the longitudinal direction. Transversely, the design lane load shall be assumed to be uniformly distributed over a 10.0-ft width. The force effects from the design lane load shall not be subject to a dynamic load allowance.

3.6.1.2.5—Tire Contact Area

The tire contact area of a wheel consisting of one or two tires shall be assumed to be a single rectangle, whose width is 20.0 in. and whose length is 10.0 in. The tire pressure shall be assumed to be uniformly distributed over the contact area. The tire pressure shall be assumed to be distributed as follows:

- On continuous surfaces, uniformly over the specified contact area, and

C3.6.1.2.5

The area load applies only to the design truck and tandem. For other design vehicles, the tire contact area should be determined by the Engineer.

As a guideline for other truck loads, the tire area in in.^2 may be calculated from the following dimensions:

- Tire width = $P/0.8$
- Tire length = $6.4\gamma(1 + IM/100)$

- On interrupted surfaces, uniformly over the actual contact area within the footprint with the pressure increased in the ratio of the specified to actual contact areas.

For the design of orthotropic decks and wearing surfaces on orthotropic decks, the front wheels shall be assumed to be a single rectangle whose width and length are both 10.0 in. as specified in Article 3.6.1.4.1.

3.6.1.2.6—Distribution of Wheel Load through Earth Fills

3.6.1.2.6a—General

The effects of live load shall be included in design for all culverts.

Live load shall be distributed to the top slabs of flat top three-sided concrete culverts, concrete box culverts, three-sided arch top concrete culverts, or concrete arch culverts over the area calculated in this Article, but not less than the dimensions calculated using the procedure specified in Article 4.6.2.10. Live load shall be distributed to concrete pipe culverts with less than 2.0 ft of cover in accordance with Eq. 4.6.2.10.2-1, regardless of the direction of travel. Round concrete culverts with 1.0 ft or more but less than 2.0 ft of cover shall be designed for a depth of 1.0 ft. Round culverts with less than 1.0 ft of fill shall be analyzed with more comprehensive methods such as finite element method considering soil-structure interaction.

The following procedures apply to all nonconcrete culverts with depth of fill of 1.0 ft and greater and to all other culverts as noted above. Live load shall be uniformly distributed wheel loads over a rectangular area with sides equal to the dimension of the tire contact area specified in Article 3.6.1.2.5 increased by the live load distribution factors (LLDF) specified in Table 3.6.1.2.6a-1, and the provisions of Articles 3.6.1.2.6b and 3.6.1.2.6c. More precise methods of analysis may be used.

For traffic parallel to the span, culverts shall be analyzed for a single loaded lane with the single lane multiple presence factor. For traffic perpendicular to the culvert span, analysis shall include consideration of multiple lane loadings with appropriate multiple presence factors. Only the axle loads of the design truck or design tandem of Articles 3.6.1.2.2 and 3.6.1.2.3, respectively shall be applied as live load on culverts, regardless of traffic orientation.

where:

$$\gamma = \text{load factor}$$
$$IM = \text{dynamic load allowance percent}$$
$$P = \text{design wheel load (kip)}$$

C3.6.1.2.6a

The Owner may choose to neglect the effects of live load when the factored live load vertical crown pressure at the surface of the culvert is less than 10 percent of the sum of the factored vertical earth load plus factored vertical live load crown pressure based on the results of NCHRP 15-54 (Mlynarski et al., 2020).

Elastic solutions for pressures produced within an infinite half-space by loads on the ground surface can be found in Poulos and Davis (1974), NAVFAC DM-7.1 (2022), and soil mechanics textbooks.

This approximation is similar to the 60-degree rule found in many texts on soil mechanics. The dimensions of the tire contact area are determined at the surface based on the dynamic load allowance of 33 percent at depth = 0. They are projected through the soil as specified. The pressure intensity on the surface is based on the wheel load without dynamic load allowance. A dynamic load allowance is added to the pressure on the projected area. The dynamic load allowance also varies with depth as specified in Article 3.6.2.2. The design lane load is applied where appropriate and multiple presence factors apply.

This provision applies to relieving slabs below grade and to top slabs of box culverts.

Traditionally, the effect of fills less than 2.0 ft deep on live load has been ignored. McGrath et al., 2004 show that in design of box sections allowing distribution of live load through fill in the direction parallel to the span provides a more accurate design model to predict moment, thrust, and shear forces. Provisions in Article 4.6.2.10 provide a means to address the effect of shallow fills.

Table 3.6.1.2.6a-1—Live Load Distribution Factor (LLDF) for Buried Structures

Structure Type	LLDF Transverse or Parallel to Span
Concrete Pipe with fill depth 2.0 ft or greater	1.15 for diameter 2.0 ft or less 1.75 for diameters 8.0 ft or greater Linearly interpolate for LLDF between these limits
All other culverts and buried structures	1.15

The rectangular area, A_{LL} , shall be determined as:

$$A_{LL} = \ell_w w_w \quad (3.6.1.2.6a-1)$$

The terms, ℓ_w and w_w , shall be determined as specified in Articles 3.6.1.2.6b and 3.6.1.2.6c.

3.6.1.2.6b—Traffic Parallel to the Culvert Span

C3.6.1.2.6b

For live load distribution transverse to culvert spans, the wheel/axle load interaction depth H_{int-t} shall be determined as:

$$H_{int-t} = \frac{s_w - \frac{w_t}{12} - \frac{0.06D_t}{12}}{LLDF} \quad (3.6.1.2.6b-1)$$

in which:

- where $H < H_{int-t}$:

$$w_w = \frac{w_t}{12} + LLDF(H) + 0.06 \frac{D_t}{12} \quad (3.6.1.2.6b-2)$$

- where $H \geq H_{int-t}$:

$$w_w = \frac{w_t}{12} + s_w + LLDF(H) + 0.06 \frac{D_t}{12} \quad (3.6.1.2.6b-3)$$

For live load distribution parallel to culvert span, the wheel/axle load interaction depth H_{int-p} shall be determined as:

$$H_{int-p} = \frac{s_w - \frac{l_t}{12}}{LLDF} \quad (3.6.1.2.6b-4)$$

in which:

- where $H < H_{int-p}$:

The case where traffic is parallel to the culvert span applies to the vast majority of highway culverts. The ASTM culvert standards assume at fill depths exceeding 5 feet that the direction of travel will not change the force effects on the culvert. Therefore, designers can conservatively utilize the traffic parallel to the span to determine those demands.

3.6.1.3—Application of Design Vehicular Live Loads

3.6.1.3.1—General

Unless otherwise specified, the extreme force effect shall be taken as the larger of the following:

- The effect of the design tandem combined with the effect of the design lane load, or
- The effect of one design truck with the variable axle spacing specified in Article 3.6.1.2.2, combined with the effect of the design lane load, and
- For negative moment between points of contraflexure under a uniform load on all spans, and for reaction at all interior supports of multi-span structures regardless of superstructure continuity, 90 percent of the effect of the design lane load on all spans combined with 90 percent of the effect of two design trucks spaced a minimum of 50.0 ft between the lead axle of one truck and the rear axle of the other truck. The distance between the 32.0-kip axles of each truck shall be taken as 14.0 ft. The two design trucks shall be placed in adjacent spans to produce maximum force effects.

Axles that do not contribute to the extreme force effect under consideration shall be neglected.

Both the design lanes and the 10.0-ft loaded width in each lane shall be positioned to produce extreme force effects. The design truck or tandem shall be positioned transversely such that the center of any wheel load is not closer than:

- For the design of the deck overhang—1.0 ft from the face of the curb or railing, and
- For the design of all other components—2.0 ft from the edge of the design lane.

Unless otherwise specified, the lengths of design lanes, or parts thereof, that contribute to the extreme force effect under consideration shall be loaded with the design lane load.

3.6.1.3.2—Loading for Optional Live Load Deflection Evaluation

If the Owner invokes the optional live load deflection criteria specified in Article 2.5.2.6.2, the deflection should be taken as the larger of:

- That resulting from the design truck alone, or

C3.6.1.3.1

The effects of an axle sequence and the lane load are superposed in order to obtain extreme values. This is a deviation from the traditional AASHTO approach, in which either the truck or the lane load, with an additional concentrated load, provided for extreme effects.

The lane load is not interrupted to provide space for the axle sequences of the design tandem or the design truck; interruption is needed only for patch loading patterns to produce extreme force effects.

The notional design loads were based on the information described in Article C3.6.1.2.1, which contained data on “low boy” type vehicles weighing up to about 110 kip. Where multiple lanes of heavier versions of this type of vehicle are considered probable, consideration should be given to investigating negative moment and reactions at interior supports for pairs of the design tandem spaced from 26.0 ft to 40.0 ft apart, combined with the design lane load specified in Article 3.6.1.2.4. The design tandems should be placed in adjacent spans to produce maximum force effect. One hundred percent of the combined effect of the design tandems and the design lane load should be used. This is consistent with Article 3.6.1.2.1 and should not be considered a replacement for the Strength II Load Combination.

Only those areas or parts of areas that contribute to the same extreme being sought should be loaded. The loaded length should be determined by the points where the influence surface meets the centerline of the design lane.

The HL-93 live load model was found to be appropriate for global analysis of long-span bridges (Nowak, 2010). In general, the design lane load portion of the HL-93 design load, which is the major contributor to live load force effects for long loaded lengths, is conservative. The conservatism is generally acceptable since members with long loaded lengths typically have much larger dead load than the live load. The conservatism could be somewhat less where the dead load has been mitigated, such as with cambered stiffening trusses on suspension bridges.

Where a sidewalk is not separated from the roadway by a crashworthy traffic barrier, consideration should be given to the possibility that vehicles can mount the sidewalk.

C3.6.1.3.2

As indicated in C2.5.2.6.1, live load deflection is a service issue, not a strength issue. Experience with bridges designed under previous editions of the *AASHTO Standard Specifications for Highway Bridges* indicated no adverse effects of live load deflection per se. Therefore, there

- That resulting from 25 percent of the design truck taken together with the design lane load.

appears to be little reason to require that the past criteria be compared to a deflection based upon the heavier live load required by these Specifications.

The provisions of this Article are intended to produce apparent live load deflections similar to those used in the past. The current design truck is identical to the HS-20 truck of past Standard Specifications. For the span lengths where the design lane load controls, the design lane load together with 25 percent of the design truck, i.e., three concentrated loads totaling 18.0 kip, is similar to the past lane load with its single concentrated load of 18.0 kip.

3.6.1.3.3—Design Loads for Decks, Deck Systems, and the Top Slabs of Box Culverts

The provisions of this Article shall not apply to decks designed under the provisions of Article 9.7.2.

Where the approximate strip method is used to analyze decks and top slabs of culverts, force effects shall be determined on the following basis:

- Where the slab spans primarily in the transverse direction, only the axles of the design truck of Article 3.6.1.2.2 or design tandem of Article 3.6.1.2.3 shall be applied to the deck slab or the top slab of box culverts.
- Where the slab spans primarily in the longitudinal direction:
 - For top slabs of box culverts of all spans and for all other cases, including slab-type bridges where the span does not exceed 15.0 ft, only the axle loads of the design truck or design tandem of Articles 3.6.1.2.2 and 3.6.1.2.3, respectively, shall be applied.
 - For all other cases, including slab-type bridges (excluding top slabs of box culverts) where the span exceeds 15.0 ft, all of the load specified in Article 3.6.1.2 shall be applied.

Where the refined methods are used to analyze decks, force effects shall be determined on the following basis:

- Where the slab spans primarily in the transverse direction, only the axles of the design truck of Article 3.6.1.2.2 or design tandem of Article 3.6.1.2.3 shall be applied to the deck slab.
- Where the slab spans primarily in the longitudinal direction (including slab-type bridges), all of the loads specified in Article 3.6.1.2 shall be applied.

Wheel loads shall be assumed to be equal within an axle unit, and amplification of the wheel loads due to centrifugal and braking forces need not be considered for the design of decks.

C3.6.1.3.3

This Article clarifies the selection of wheel loads to be used in the design of bridge decks, slab bridges, and top slabs of box culverts.

The design load is always an axle load; single wheel loads should not be considered.

The design truck and tandem without the lane load and with a multiple presence factor of 1.2 results in factored force effects that are similar to the factored force effects using earlier specifications for typical span ranges of box culverts.

Individual Owners may choose to develop other axle weights and configurations to capture the load effects of the actual loads in their jurisdiction based upon local legal-load and permitting policies. Triple-axle configurations of single unit vehicles have been observed to have load effects in excess of the HL-93 tandem axle load.

It is theoretically possible that an extreme force effect could result from a 32.0-kip axle in one lane and a 50.0-kip tandem in a second lane, but such sophistication is not warranted in practical design.

3.6.1.3.4—Deck Overhang Load

For the design of deck overhangs with a cantilever, not exceeding 6.0 ft from the centerline of the exterior girder to the face of a structurally continuous concrete railing, the outside row of wheel loads may be replaced with a uniformly distributed line load of 1.0 klf intensity, located 1.0 ft from the face of the railing.

Horizontal loads on the overhang resulting from vehicle collision with barriers shall be in accordance with the provisions of Section 13.

3.6.1.4—Fatigue Load

3.6.1.4.1—Magnitude and Configuration

The fatigue load shall be one design truck or axles thereof specified in Article 3.6.1.2.2, but with a constant spacing of 30.0 ft between the 32.0-kip axles.

The dynamic load allowance specified in Article 3.6.2 shall be applied to the fatigue load.

For the design of orthotropic decks and wearing surfaces on orthotropic decks, the loading pattern as shown in Figure 3.6.1.4.1-1 shall be used.

C3.6.1.3.4

Structurally continuous barriers have been observed to be effective in distributing wheel loads in the overhang. Implicit in this provision is the assumption that the 25.0-kip half weight of a design tandem is distributed over a longitudinal length of 25.0 ft, and that there is a cross beam or other appropriate component at the end of the bridge supporting the barrier which is designed for the half tandem weight. This provision does not apply if the barrier is not structurally continuous.

C3.6.1.4.1

For orthotropic steel decks, the governing 16.0-kip wheel loads should be modeled in more detail as two closely spaced 8.0-kip wheels 4.0 ft apart to more accurately reflect a modern tractor-trailer with tandem rear axles. Further, these wheel loads should be distributed over the specified contact area (20.0 in. wide $\times$ 10.0 in. long for rear axles and 10.0 in. square for front axles), which better approximates actual pressures applied from a dual tire unit (Kulicki and Mertz, 2006). Note that the smaller 10.0 in. $\times$ 10.0 in. front wheels can be the controlling load for fatigue design of many orthotropic deck details.

This loading should be positioned both longitudinally and transversely on the bridge deck, ignoring the striped lanes, to create the worst stress or deflection, as applicable.

Figure 3.6.1.4.1-1—Refined Design Truck Footprint for Fatigue Design of Orthotropic Decks

3.6.1.4.2—Frequency

The frequency of the fatigue load shall be taken as the single-lane average daily truck traffic, $ADTT_{SL}$. This frequency shall be applied to all components of the bridge, even to those located under lanes that carry a lesser number of trucks.

In the absence of better information, the single-lane average daily truck traffic shall be taken as:

C3.6.1.4.2

Since the fatigue and fracture limit state is defined in terms of accumulated stress-range cycles, specification of load alone is not adequate. Load should be specified along with the frequency of load occurrence.

For the purposes of this Article, a truck is defined as any vehicle with more than either two axles or four wheels.

$$ADTT_{SL} = p \times ADTT \quad (3.6.1.4.2-1)$$

where:

- $ADTT$ = the number of trucks per day in one direction averaged over the design life
- $ADTT_{SL}$ = the number of trucks per day in a single-lane averaged over the design life
- p = fraction of traffic in a single lane, taken as specified in Table 3.6.1.4.2-1

The single-lane $ADTT$ is that for the traffic lane in which the majority of the truck traffic crosses the bridge. On a typical bridge with no nearby entrance/exit ramps, the shoulder lane carries most of the truck traffic. The frequency of the fatigue load for a single lane is assumed to apply to all lanes since future traffic patterns on the bridge are uncertain.

Consultation with traffic engineers regarding any directionality of truck traffic may lead to the conclusion that one direction carries more than one-half of the bidirectional $ADTT$. If such data is not available from traffic engineers, designing for 55 percent of the bidirectional $ADTT$ is suggested.

The value of $ADTT_{SL}$ is best determined in consultation with traffic engineers. However, traffic growth data is usually not predicted for the design life of the bridge, taken as 75 years in these Specifications unless specified otherwise by the Owner. Techniques exist to extrapolate available data such as curve fitting growth rate vs. time and using extreme value distributions, but some judgment is required. Research has shown that the average daily traffic (ADT) including all vehicles, i.e., cars and trucks, is physically limited to about 20,000 vehicles per lane per day under normal conditions. This limiting value of traffic should be considered when estimating the $ADTT$. The $ADTT$ can be determined by multiplying the ADT by the fraction of trucks in the traffic. In lieu of site-specific fraction of truck traffic data, the values of Table C3.6.1.4.2-1 may be applied for routine bridges.

Table 3.6.1.4.2-1—Fraction of Truck Traffic in a Single Lane, p

Number of Lanes Available to Trucks	P
1	1.00
2	0.85

3.6.1.4.3—Load Distribution for Fatigue

3.6.1.4.3a—Refined Methods

Where the bridge is analyzed by any refined method, as specified in Article 4.6.3, a single design truck shall be positioned transversely and longitudinally to maximize stress range at the detail under consideration, regardless of the position of traffic or design lanes on the deck.

3.6.1.4.3b—Approximate Methods

Where the bridge is analyzed by approximate load distribution, as specified in Article 4.6.2, the distribution factor for one traffic lane shall be used.

Table C3.6.1.4.2-1—Fraction of Trucks in Traffic

Class of Highway	Fraction of Trucks in Traffic
Rural Interstate	0.20
Urban Interstate	0.15
Other Rural	0.15
Other Urban	0.10

C3.6.1.4.3a

If it were assured that the traffic lanes would remain as they are indicated at the opening of the bridge throughout its entire service life, it would be more appropriate to place the truck at the center of the traffic lane that produces maximum stress range in the detail under consideration. But because future traffic patterns on the bridge are uncertain and in the interest of minimizing the number of calculations required of the Designer, the position of the truck is made independent of the location of both the traffic lanes and the design lanes.

3.6.1.5—Rail Transit Load

Where a bridge also carries rail-transit vehicles, the Owner shall specify the transit load characteristics and the expected interaction between transit and highway traffic.

C3.6.1.5

If rail transit is designed to occupy an exclusive lane, transit loads should be included in the design, but the bridge should not have less strength than if it had been designed as a highway bridge of the same width.

If the rail transit is supposed to mix with regular highway traffic, the Owner should specify or approve an appropriate combination of transit and highway loads for the design.

Transit load characteristics may include:

- loads,
- load distribution,
- load frequency,
- dynamic allowance, and
- dimensional requirements.

3.6.1.6—Pedestrian Loads

A pedestrian load of 0.075 ksf shall be applied to all sidewalks wider than 2.0 ft simultaneously with the vehicular design live load in the vehicle lane. Where vehicles can mount the sidewalk, the pedestrian load shall not act concurrently with the vehicle load. If a sidewalk may be removed in the future, apply vehicular loads as specified in Article 3.6.1.3.1.

Bridges intended for only pedestrian, equestrian, light maintenance vehicle, and/or bicycle traffic should be designed in accordance with AASHTO's *LRFD Guide Specifications for the Design of Pedestrian Bridges*.

C3.6.1.6

See the provisions of Article C3.6.1.1.2 for applying the pedestrian loads in combination with the vehicular live load.

3.6.1.7—Loads on Railings

Loads on railings shall be taken as specified in Section 13.

3.6.2—Dynamic Load Allowance: *IM*

3.6.2.1—General

Unless otherwise permitted in Articles 3.6.2.2 and 3.6.2.3, the static effects of the design truck or tandem, other than centrifugal and braking forces, shall be increased by the percentage specified in Table 3.6.2.1-1 for dynamic load allowance.

The factor to be applied to the static load shall be taken as: $(1 + IM/100)$.

The dynamic load allowance shall not be applied to pedestrian loads or to the design lane load.

C3.6.2.1

Page (1976) contains the basis for some of these provisions.

The dynamic load allowance (*IM*) in Table 3.6.2.1-1 is an increment to be applied to the static wheel load to account for wheel load impact from moving vehicles.

Dynamic effects due to moving vehicles may be attributed to two sources:

- hammering effect is the dynamic response of the wheel assembly to riding surface discontinuities, such as deck joints, cracks, potholes, and delaminations, and
- dynamic response of the bridge as a whole to passing vehicles, which may be due to long undulations in the roadway pavement, such as those caused by settlement of fill, or to resonant excitation as a result of similar frequencies of vibration between bridge and vehicle.

Table 3.6.2.1-1—Dynamic Load Allowance, *IM*

Component	<i>IM</i>
Deck Joints—All Limit States	75%
All Other Components:	
• Fatigue and Fracture Limit State	15%
• All Other Limit States	33%

The application of dynamic load allowance for buried components, covered in Section 12, shall be as specified in Article 3.6.2.2.

Dynamic load allowance need not be applied to:

- retaining walls not subject to vertical reactions from the superstructure, and
- foundation components that are entirely below ground level.

The dynamic load allowance may be reduced for components, other than joints, if justified by sufficient evidence, in accordance with the provisions of Article 4.7.2.1.

Field tests indicate that in the majority of highway bridges, the dynamic component of the response does not exceed 25 percent of the static response to vehicles. This is the basis for dynamic load allowance with the exception of deck joints. However, the specified live load combination of the design truck and lane load, represents a group of exclusion vehicles that are at least 4/3 of those caused by the design truck alone on short- and medium-span bridges. The specified value of 33 percent in Table 3.6.2.1-1 is the product of 4/3 and the basic 25 percent.

Generally speaking, the dynamic amplification of trucks follows the following general trends:

- As the weight of the vehicle goes up, the apparent amplification goes down.
- Multiple vehicles produce a lower dynamic amplification than a single vehicle.
- More axles result in a lower dynamic amplification.

For heavy permit vehicles which have many axles compared to the design truck, a reduction in the dynamic load allowance may be warranted. A study of dynamic effects presented in a report by the Calibration Task Group (Nowak, 1992) contains details regarding the relationship between dynamic load allowance and vehicle configuration.

This Article recognizes the damping effect of soil when in contact with some buried structural components, such as footings. To qualify for relief from impact, the entire component must be buried. For the purpose of this Article, a retaining type component is considered to be buried to the top of the fill.

3.6.2.2—Buried Components

The dynamic load allowance for culverts and other buried structures covered by Section 12, in percent, shall be taken as:

$$IM = 33(1.0 - 0.125D_E) \geq 0\% \quad (3.6.2.2-1)$$

where:

D_E = the minimum depth of earth cover above the structure (ft)

3.6.2.3—Wood Components

Dynamic load allowance need not be applied to wood components.

C3.6.2.3

Wood structures are known to experience reduced dynamic wheel load effects due to internal friction between the components and the damping characteristics of wood. Additionally, wood is stronger for short duration loads, as compared to longer duration loads. This increase in strength is greater than the increase in force effects resulting from the dynamic load allowance.

3.6.3—Centrifugal Forces: *CE*

For the purpose of computing the radial force or the overturning effect on wheel loads, the centrifugal effect on live load shall be taken as the product of the axle weights of the design truck or tandem and the factor, C , taken as:

$$C = f \frac{v^2}{gR} \quad (3.6.3-1)$$

where:

- v = highway design speed (ft/s)
- f = $\frac{4}{3}$ for load combinations other than fatigue and 1.0 for fatigue
- g = gravitational acceleration: 32.2 (ft/s²)
- R = radius of curvature of traffic lane (ft)

Highway design speed shall not be taken to be less than the value specified in the current edition of AASHTO's *A Policy of Geometric Design of Highways and Streets*.

The multiple presence factors specified in Article 3.6.1.1.2 shall apply.

Centrifugal forces shall be applied horizontally at a distance 6.0 ft above the roadway surface. A load path to carry the radial force to the substructure shall be provided.

The effect of superelevation in reducing the overturning effect of centrifugal force on vertical wheel loads may be considered.

3.6.4—Braking Force: *BR*

The braking force shall be taken as the greater of:

- 25 percent of the axle weights of the design truck or design tandem, or
- Five percent of the design truck plus lane load or five percent of the design tandem plus lane load

This braking force shall be placed in all design lanes which are considered to be loaded in accordance with Article 3.6.1.1.1 and which are carrying traffic headed in the same direction. These forces shall be assumed to act horizontally at a distance of 6.0 ft above the roadway surface in either longitudinal direction to cause extreme force effects. All design lanes shall be simultaneously loaded for bridges likely to become one-directional in the future.

The multiple presence factors specified in Article 3.6.1.1.2 shall apply.

C3.6.3

Centrifugal force is not required to be applied to the design lane load, as the spacing of vehicles at high speed is assumed to be large, resulting in a low density of vehicles following and/or preceding the design truck. For all other consideration of live load other than for fatigue, the design lane load is still considered even though the centrifugal effect is not applied to it.

The specified live load combination of the design truck and lane load, however, represents a group of exclusion vehicles that produce force effects of at least $\frac{4}{3}$ of those caused by the design truck alone on short- and medium-span bridges. This ratio is indicated in Eq. 3.6.3-1 for the service and strength limit states. For the fatigue and fracture limit state, the factor 1.0 is consistent with cumulative damage analysis. The provision is not technically perfect, yet it reasonably models the representative exclusion vehicle traveling at design speed with large headways to other vehicles. The approximation attributed to this convenient representation is acceptable in the framework of the uncertainty of centrifugal force from random traffic patterns.

$$1.0 \text{ ft/s} = 0.682 \text{ mph}$$

Centrifugal force also causes an overturning effect on the wheel loads because the radial force is applied 6.0 ft above the top of the deck. Thus, centrifugal force tends to cause an increase in the vertical wheel loads toward the outside of the bridge and an unloading of the wheel loads toward the inside of the bridge. Superelevation helps to balance the overturning effect due to the centrifugal force and this beneficial effect may be considered. The effects due to vehicle cases with centrifugal force effects included should be compared to the effects due to vehicle cases with no centrifugal force, and the worst case selected.

C3.6.4

Based on energy principles, and assuming uniform deceleration, the braking force determined as a fraction of vehicle weight is:

$$b = \frac{v^2}{2ga} \quad (C3.6.4-1)$$

Where a is the length of uniform deceleration and b is the fraction. Calculations using a braking length of 400 ft and a speed of 55 mph yield $b = 0.25$ for a horizontal force that will act for a period of about 10 s. The factor b applies to all lanes in one direction because all vehicles may have reacted within this time frame.

For short- and medium-span bridges, the specified braking force can be significantly larger than was required in the AASHTO *Standard Specifications for Highway Bridges*. The braking force specified in the Standard Specifications dates back to at least the early 1940s without any significant changes to address the improved braking

capacity of modern trucks. A review of other bridge design codes in Canada and Europe shows that the braking force required by the Standard Specifications is much lower than that specified in other design codes for most typical bridges. One such comparison is shown in Figure C3.6.4-1.

Figure C3.6.4-1—Comparison of Braking Force Models

Figure C3.6.4-1 (cont.)—Comparison of Braking Force Models

where:

- OHBDC = factored braking force as specified in the 3rd edition of the *Ontario Highway Bridge Design Code*
- LFD = factored braking force as specified in the AASHTO Standard Specifications (Load Factor)
- LRFD = factored braking force as originally specified in the early versions of the LRFD Specifications (up to the 2001 Interim edition)
- LRFD' = factored braking force, as specified in Article 3.6.4
- CHBDC = factored braking force as specified in the *Canadian Highway Bridge Design Code*

The sloping portion of the curves represents the braking force that includes a portion of the lane load. This represents the possibility of having multiple lanes of vehicles contributing to the same braking event on a long bridge. Although the probability of such an event is likely to be small, the inclusion of a portion of the lane load gives such an event consideration for bridges with heavy truck traffic and is consistent with other design codes.

Because the LRFD braking force is significantly higher than that required in the Standard Specifications, this issue becomes important in rehabilitation projects designed under previous versions of the design code. In cases where substructures are found to be inadequate to resist the increased longitudinal forces, consideration should be given to design and detailing strategies which distribute the braking force to additional substructure units during a braking event.

3.6.5—Vehicular Collision Force: *CT*

3.6.5.1—Protection of Structures

Unless the Owner determines that site conditions indicate otherwise, abutments and piers located within the clear zone as defined by the *AASHTO Roadside Design Guide* shall be investigated for collision. Collision shall be addressed by either providing structural resistance or by

C3.6.5.1

Where an Owner chooses to make an assessment of site conditions for the purpose of implementing this provision, input from highway or highway safety engineers and structural engineers should be part of that assessment. These provisions address only protection of

redirecting or absorbing the collision load. The provisions of Article 2.3.2.2.1 shall apply as appropriate.

Where the design choice is to provide structural resistance, the pier or abutment shall be designed for an equivalent static force of 600 kip, which is assumed to act in a direction of zero to 15 degrees with the edge of the pavement in a horizontal plane, at a distance from 2.0 to 5.0 ft above the ground, whichever produces the critical shear or moment in the pier component and the connections to the foundation or pier cap.

Each of the following substructure components are considered to have adequate structural resistance to bridge collapse due to vehicular impacts and are not required to be designed for the vehicular impact load:

1. Substructure components that are backed by soil (e.g., most abutments).
2. Reinforced concrete pier components that are at least 3.0-ft thick and have a concrete cross-sectional area greater than 30.0 ft² as measured in the horizontal plane at all elevations from the top of the pier foundation to a height of at least 5.0 ft above the grade.
3. Superstructure and substructures that are designed to satisfy Extreme Event II loading combination with any single column missing from piers or bents located in the clear zone.
4. Pier walls and multi-column piers with struts between columns that have been designed and detailed as Manual for Assessing Safety Hardware (MASH) Test Level 5 (TL-5) longitudinal traffic barriers, according to Section 13.

Where the design choice is to redirect or absorb the collision load, protection shall consist of the following:

For new or retrofit construction, a minimum 42.0-in. high MASH crash tested rigid TL-5 barrier located such that the top edge of the traffic face of the barrier is 3.25 ft or more from the face of the pier component being protected.

Such rigid barriers shall be structurally and geometrically capable of surviving the crash test for MASH TL-5, as specified in Section 13.

the pier. Guidance on occupant protection during an impact with a pier or other rigid object is included in the *AASHTO Roadside Design Guide*.

The equivalent static force of 600 kip is based on the information from full-scale crash tests of rigid columns impacted by 80.0-kip tractor trailers at 50 mph as well as finite element simulations of 80.0-kip tractor trailer trucks striking pier columns. The testing and analysis reveal that there are two distinct peak load impacts. One is associated with the engine striking the pier at a height of 2.0 ft and the other with the back of the cab/front of the trailer striking the pier at a height of 5.0 ft. For individual column shafts, the 600-kip load should be considered a point load. Field observations indicate shear failures are one important mode of failure for individual columns but field observations have also indicated that flexural failures and failures between the column and cap or the column and footing can sometimes occur depending on the detailing. The designer should examine not only the shear capacity of the column but should also verify by calculation that the flexural capacity and connections are sufficient for the 600-kip design impact load. Columns that are 30.0 in. in diameter and smaller are the most vulnerable to impacts. The load may be considered to be a point load or may be distributed over an area deemed suitable for the size of the structure and the anticipated impacting vehicle, but not greater than 5.0 ft wide by 2.0 ft high centered around the assumed impact point. These dimensions were determined by considering the size of a truck frame.

For piers designed by the performance-based approach that also incorporates effects of dynamic loading, designers are encouraged to refer to the three-pulse equation approach developed by Agrawal et al. (2018) and Cao et al. (2019, 2020). This approach allows a designer to achieve a targeted level of performance for a bridge pier during vehicular impact, from minor to severe damage.

Requirements for train collision load found in previous editions have been removed. Designers are encouraged to consult the AREMA *Manual for Railway Engineering* or local railroad company guidelines for train collision requirements.

For the purpose of this Article, a barrier may be considered structurally independent if it does not transmit loads to the bridge.

Editions of these Specifications prior to the 9th (2020) indicated that if pier components were located closer than 10.0 ft from the shielding barrier a 54.0 in. tall barrier should be used. Full-scale crash tests and finite element simulations indicate that the modern trailer suspensions result in much more stable impacts than was the case in crash tests of older trailer suspensions. If a trailer does lean over the barrier and contact a pier component, the interaction will not involve the entire mass of the vehicle and is unlikely to develop sufficient impact forces to put the pier system at risk of failure. It is preferable to allow 3.25 ft of space between the top traffic face of the barrier and the face of the nearest pier component to minimize contact with a heavy vehicle. In some retrofit situations, however, it may be impossible to

provide this amount of space given the existing pier location and arrangement of the roadway. In such cases it is permissible to place the barrier closer to the face of at-risk pier components.

One way to determine whether site conditions qualify for exemption from protection is to evaluate the annual frequency of bridge collapse from impacts with heavy vehicles. With the approval of the Owner, the expected annual frequency of bridge collapse, AF_{BC} , can be calculated as follows:

1. Identify each approach direction, i , where a pier component is at risk of an impact from approaching traffic.
2. Calculate the annual frequency of bridge collapse as follows:

$$AF_{BC} = \sum_{i=1}^m N_i \cdot HVE_i \cdot P(C|HVE_i) \cdot P(Q_{CT} > R_{CPC}|C) \quad (C3.6.5.1-1)$$

where:

- N_i = the site-specific adjustment factor, N_i , computed from values in Table C3.6.5.1-1
- HVE_i = the heavy vehicle base encroachment frequency from Table C3.6.5.1-2
- $P(C|HVE_i)$ = the probability of a collision given a heavy vehicle encroachment from Table C3.6.5.1-3
- $P(Q_{CT} > R_{CPC}|C)$ = the probability of the worst-case collision force, Q_{CT} (kip), exceeding the critical pier component capacity, R_{CPC} (kip), from Table C3.6.5.1-4

Design for vehicular collision force is not required if the annual frequency of bridge collapse, AF_{BC} , is less than 0.0001 for critical or essential bridges or 0.001 for typical bridges. If the annual frequency of bridge collapse, AF_{BC} , is greater than or equal to 0.0001 for critical or essential bridges or 0.001 for typical bridges and the pier components are not designed to resist vehicular collision forces, then the pier system must be shielded as described in Article 3.6.5.1.

The thresholds for AF_{BC} mirror those for vessel collision force found in Article 3.14.5.

Table C3.6.5.1-1—Site Specific Adjustment Factor, N_i

Major Accesses [‡]			Lane Width			Horizontal Curve Radius [†]	
Number of Access Points within 300 ft upstream of the pier system	Undivided	Divided and One-way	Avg. Lane Width in feet	Undivided	Divided and One-way	Horizontal Curve Radius at Centerline in feet	All Highway Types

N _i = f _{ACC} f _{LN} f _{LW} f _G f _{HC} f _{PSL} =							

‡ Major accesses include ramps and intersections. Commercial and residential driveways should not be included as access points unless they are signalized or stop-sign controlled.

† The horizontal curve radius may either curve away (AR) from the pier system under consideration or toward it (TR). When the driver is turning the wheel of the vehicle away from the pier, the AR adjustments shall be used. When the driver is turning the wheel of the vehicle toward the pier, the TR adjustments should be used. This adjustment must be considered for each direction of travel, i , where an encroaching vehicle could approach the pier system.

†† The grade approaching the pier system must be considered for each direction of travel, i . Positive grades indicate an uphill grade and negative values indicate a downhill grade.

¶ For roads with unposted speed limits, use the adjustment for <65 mi/hr.

3.6.5.2—Vehicle Collision with Barriers

The provisions of Section 13 shall apply.

For assessing the strength and geometry of a rigid barrier used for pier component protection, Section 13 shall apply. The provisions of Article 2.3.2.2.1 shall apply as is appropriate, except if an independently supported rigid MASH TL-5 barrier is used it shall be placed such that there is at least 3.25 ft between the traffic face of the barrier and the nearest face of the pier component. Barriers used for pier protection shall be MASH tested TL-5 rigid concrete barriers.

Barriers should be placed on the site according to the recommendations of the *AASHTO Roadside Design Guide*. The MASH TL-5 rigid shielding barrier must be at least 42.0 in. tall. A minimum barrier length of 60.0 ft upstream of the leading edge of the pier system plus the entire length of the pier system shall be shielded.

C3.6.5.2

For retrofit construction, a minimum 42.0-in. high MASH crash tested rigid TL-5 barrier may be placed closer than 3.25 ft from the top edge of the traffic face of the barrier to the nearest traffic face of the pier component being protected when there is no other practical option.

3.7—WATER LOADS: *WA***3.7.1—Static Pressure**

Static pressure of water shall be assumed to act perpendicular to the surface that is retaining the water. Pressure shall be calculated as the product of height of water above the point of consideration and the specific weight of water.

Design water levels for various limit states shall be as specified and/or approved by the Owner.

3.7.2—Buoyancy

Buoyancy shall be considered to be an uplift force, taken as the sum of the vertical components of static pressures, as specified in Article 3.7.1, acting on all components below design water level.

C3.7.2

For substructures with cavities in which the presence or absence of water cannot be ascertained, the condition producing the least favorable force effect should be chosen.

3.7.3—Stream Pressure**3.7.3.1—Longitudinal**

The pressure of flowing water acting in the longitudinal direction of substructures shall be taken as:

$$p = \frac{C_D V^2}{1,000} \quad (3.7.3.1-1)$$

where:

p = pressure of flowing water (ksf)
 C_D = drag coefficient for piers, as specified in Table 3.7.3.1-1

C3.7.3.1

For the purpose of this Article, the longitudinal direction refers to the major axis of a substructure unit.

The theoretically correct expression for Eq. 3.7.3.1-1 is:

$$p = C_D \frac{w}{2g} V^2 \quad (C3.7.3.1-1)$$

where:

w = specific weight of water (kcf)
 V = velocity of water (ft/s)

V = design velocity of water for the design flood in strength and service limit states and for the check flood in the extreme event limit state (ft/s)

Table 3.7.3.1-1—Drag Coefficient

Type	C_D
Semicircular-nosed pier	0.7
Square-ended pier	1.4
Debris lodged against the pier	1.4
Wedged-nosed pier with nose angle 90 degrees or less	0.8

The longitudinal drag force shall be taken as the product of longitudinal stream pressure and the projected surface exposed thereto.

g = gravitational acceleration constant—32.2 (ft/s²)

As a convenience, Eq. 3.7.3.1-1 recognizes that $w/2g \sim 1/1,000$, but the dimensional consistency is lost in the simplification.

The drag coefficient, C_D , and the lateral drag coefficient, C_L , given in Tables 3.7.3.1-1 and 3.7.3.2-1, were adopted from the OHBDC (1991). The more favorable drag coefficients measured by some researchers for wedge-type pier nose angles of less than 90 degrees are not given here because such pier noses are more prone to catching debris.

Floating logs, roots, and other debris may accumulate at piers and, by blocking parts of the waterway, increase stream pressure load on the pier. Such accumulation is a function of the availability of such debris and level of maintenance efforts by which it is removed. It may be accounted for by the judicious increase in both the exposed surface and the velocity of water.

The following provisions were considered in the late 1980s for use in the New Zealand Highway Bridge Design Specification (Transit New Zealand, 1991). These provisions may be used as guidance in the absence of site-specific criteria:

Where a significant amount of driftwood is carried, water pressure shall also be allowed for on a driftwood raft lodged against the pier. The size of the raft is a matter of judgment, but as a guide, Dimension A in Figure C3.7.3.1-1 should be half the water depth, but not greater than 10.0 ft. Dimension B should be half the sum of adjacent span lengths, but no greater than 45.0 ft. Pressure shall be calculated using Eq. 3.7.3.1-1, with $C_D = 0.5$. (Distances have been changed from SI.)

Figure C3.7.3.1-1—Debris Raft for Pier Design

3.7.3.2—Lateral

The lateral, uniformly distributed pressure on a substructure due to water flowing at an angle, θ , to the longitudinal axis of the pier shall be taken as:

C3.7.3.2

The discussion of Eq. 3.7.3.1-1 also applies to Eq. 3.7.3.2-1.

$$p = \frac{C_L V^2}{1,000} \quad (3.7.3.2-1)$$

where:

p = lateral pressure (ksf)
 C_L = lateral drag coefficient, specified in Table 3.7.3.2-1

Figure 3.7.3.2-1—Plan View of Pier Showing Stream Flow Pressure

Table 3.7.3.2-1—Lateral Drag Coefficient

Angle, θ , between direction of flow and longitudinal axis of the pier	C_L
0 degrees	0.0
5 degrees	0.5
10 degrees	0.7
20 degrees	0.9
≥ 30 degrees	1.0

The lateral drag force shall be taken as the product of the lateral stream pressure and the surface exposed thereto.

3.7.4—Wave Load

Wave action on bridge structures shall be considered for exposed structures where the development of significant wave forces may occur.

C3.7.4

Loads due to wave action on bridge structures shall be determined using accepted engineering practice methods. Site-specific conditions should be considered. The latest editions of *AASHTO Guide Specifications for Bridges Vulnerable to Coastal Storms*, the *Coastal Engineering Manual*, published by the U.S. Army Engineer Research and Development Center, or FHWA's *Hydraulic Engineering Circular 25* (HEC-25) may be utilized for the computation of wave forces.

3.8—WIND LOAD: W_L AND W_S

3.8.1—Horizontal Wind Load

3.8.1.1—Exposure Conditions

3.8.1.1.1—General

Wind pressure shall be assumed to be uniformly distributed on the area exposed to the wind. The exposed area shall be the sum of areas of all components, including floor system, railing, and sound barriers, as seen in elevation taken perpendicular to the wind direction. The wind load shall be the product of

C3.8.1.1.1

For most bridges, the same wind pressure will be used for all components of the structure and the wind load is applied as a uniformly distributed load on the entire exposed area of the structure. However, some situations may warrant using different wind pressures on different components. The most common cases are for

the wind pressure and exposed area. The wind shall be assumed horizontal, except as otherwise specified in Article 3.8.2, and can come from any horizontal direction. Areas that do not contribute to the extreme force effect under consideration may be neglected in the analysis.

For typical bridges, wind loads on the substructure from the superstructure may be determined for the wind in the direction transverse to the bridge in elevation then adjusted for various angles of attack using the provisions of Article 3.8.1.2.3a.

3.8.1.1.2—Wind Speed

The design 3-second gust wind speed, V , used in the determination of design wind loads on bridges shall be determined from Figure 3.8.1.1.2-1. For areas designated as a special wind region in Figure 3.8.1.1.2-1, the Owner shall approve the 3-second gust wind speed.

The wind speed shall be increased where records, experience, or site-specific wind studies indicate that wind speeds higher than those reflected in Figure 3.8.1.1.2-1, based upon seven percent probability of exceedance in 50 years, are possible at the bridge location.

Unless a site-specific wind study is performed, wind speeds used for different load combinations shall be taken from Table 3.8.1.1.2-1.

Table 3.8.1.1.2-1—Design 3-Second Gust Wind Speed for Different Load Combinations, V

Load Combination	3-Second Gust Wind Speed (mph), V
Strength III	Wind speed, taken from Figure 3.8.1.1.2-1
Strength V	80
Service I	70
Service IV	0.75 of the speed used for the Strength III limit state

long bridges or when the substructure is unusually tall which may warrant using different structure heights in determining the wind pressure on different portions of the superstructure or substructure.

C3.8.1.1.2

Previous editions of these Specifications were based on fastest-mile wind speed. Since that criteria was based on distance, the effect was to average the wind speed over different lengths of time. The fastest-mile wind speed is no longer utilized by modern wind codes and the provisions herein are based on 3-second gust wind speed which means that the wind speed is averaged over 3 seconds.

Figure 3.8.1.1.2-1 shows the reference 3-second gust wind speed, at an elevation of 33.0 ft, for wind exposure Category C, as defined in Article 3.8.1.1.5, with a mean recurrence interval (MRI) of 700 years. The figure is taken from ASCE 7-10 (2010).

The wind pressure determined using the design 3-second gust wind speed with a load factor of 1.0 replaces the wind pressure determined in past specifications using fastest-mile wind speed with a MRI of 100 years and a load factor of 1.4. This is the reason the load factor for wind load on the structure, WS , in the Strength III load combination has been reduced from the 1.4 used in earlier editions of the specifications to the 1.0 currently shown. The change in the load factor was instituted when the design wind speed was changed from the fastest-mile wind used earlier to the design 3-second gust wind speeds shown in Figure 3.8.1.1.2-1.

The basis for the wind speeds specified for Strength V, Service I, and Service IV limit states is presented in Article C3.4.1.

For buildings and other structures, local building officials typically determine the 3-second gust wind speed to be used in the special wind regions under their jurisdiction. Bridge Owners will need to develop their own policy for the 3-second gust wind speed to be used in these regions.

Notes:

1. Values are nominal design 3-second gust wind speeds in miles per hour (m/s) at 33 ft (10m) above ground for Exposure C category.
2. Linear interpolation between contours is permitted.
3. Islands and coastal areas outside the last contour shall use the last wind speed contour of the coastal area.
4. Mountainous terrain, gorges, ocean promontories, and special wind regions shall be examined for unusual wind conditions.
5. Wind speeds correspond to approximately a 7% probability of exceedance in 50 years (Annual Exceedance Probability = 0.00143, MRI = 700 Years).

Figure 3.8.1.1.2-1—Design Wind Speed, V , in mph (m/s)

Figure 3.8.1.1.2-1 (cont'd.)—Design Wind Speed, V , in mph (m/s)

3.8.1.1.3—Wind Direction for Determining Wind Exposure Category

For each wind direction to be investigated, the wind exposure category of the bridge shall be determined for the two upwind sectors extending 45 degrees to either side of wind direction. The wind exposure category in the two sectors shall be determined in accordance with Articles 3.8.1.1.4 and 3.8.1.1.5. The wind exposure category which results in higher wind loads shall be used in determining the wind load for wind blowing from the direction being investigated.

For typical bridges, the wind exposure category as specified in Article 3.8.1.1.5 shall be perpendicular to the bridge. For long span bridges and for high level bridges, different wind exposure categories shall be investigated to determine the most critical wind direction.

C3.8.1.1.3

For a given bridge, the ground surface roughness category may be different for different wind directions based on the obstructions that exist along the direction of the wind. However, for typical bridges, the difference in wind pressure will not be significant and determining the wind exposure category perpendicular to the bridge is sufficient.

Determining various wind exposure categories may be warranted for long spans and high level bridges. In such cases, for each wind direction to be investigated, the wind exposure category of the bridge may be determined for the two upwind sectors extending 45 degrees to either side of the wind direction. The wind exposure category in the two sectors should be determined in accordance with Articles 3.8.1.1.4 and 3.8.1.1.5. The wind exposure category which results in higher wind pressure should be used in determining the wind load for wind blowing from the direction being investigated. The purpose of examining the two 45-degree sectors is to determine the maximum wind pressure associated with the wind direction being investigated.

Figure C3.8.1.1.3-1—Wind Sectors for Wind from Any Direction

3.8.1.1.4—Ground Surface Roughness Categories

A ground surface roughness within each of the 45 degree sectors defined in Article 3.8.1.1.3 shall be determined as follows:

- Ground Surface Roughness B: Urban and suburban areas, wooded areas, or other terrain with numerous closely spaced obstructions having the size of single-family dwellings or larger;
- Ground Surface Roughness C: Open terrain with scattered obstructions having heights generally less than 33.0 ft, including flat open country and grasslands; and
- Ground Surface Roughness D: Flat, unobstructed areas and water surfaces; this category includes smooth mud flats, salt flats, and unbroken ice.

C3.8.1.1.4

The ground surface roughness categories are used in determining the wind exposure category of the structure as defined in Article 3.8.1.1.5.

The ground surface roughness categories shown herein match those in ASCE 7-10 (2010). Some of the earlier editions of ASCE 7 included a separate category for urban exposure. However, for buildings, particularly tall ones, it is thought that there is not enough urban surface roughness, even in large urban areas, to develop true urban exposure conditions. Hence, the urban exposure category was eliminated from ASCE 7. However, for a low bridge in an urban area, an urban exposure could occur in nature. Using Ground Surface Roughness Category B for both urban and suburban areas results in slightly conservative wind loads for structures in urban areas.

3.8.1.1.5—Wind Exposure Categories

C3.8.1.1.5

The exposure category of the structure shall be determined as follows:

- Wind Exposure Category B: Wind Exposure Category B shall apply where the Ground Surface Roughness Category B, as defined in Article 3.8.1.1.4, prevails in the upwind direction for a distance greater than 1,500 ft for structures with a mean height of less than or equal to 33 ft, and for a distance greater than 2,600 ft or 20 times the height of the structure, whichever is greater, for structures with a mean height greater than 33 ft.
- Wind Exposure Category C: Wind Exposure Category C shall apply for all cases where Wind Exposure Categories B or D do not apply.
- Wind Exposure Category D: Wind Exposure Category D shall apply where the Ground Surface Roughness Category D, as defined in Article 3.8.1.1.4, prevails in the upwind direction for a distance greater than 5,000 ft or 20 times the height of the structure, whichever is greater. Wind Exposure Category D shall also apply where the structure is within a distance of 600 ft or 20 times the height of the structure, whichever is greater, from a Ground Surface Roughness Category D condition, even if Ground Surface Roughness Category B or C exist immediately upwind of the structure.

Where Ground Surface Roughness Category D prevails in the upwind direction—except when Ground Surface Roughness Category B or C exist for a relatively short distance immediately upwind from the structure—the effect of the presence of Ground Surface Roughness Category B or C may not be significant. Ground Surface Roughness Category D is conservatively specified for these situations.

3.8.1.2—Wind Load on Structures: *WS*

3.8.1.2.1—General

C3.8.1.2.1

The wind pressure shall be determined as:

The basis for the development of wind load provisions exists in Wassef and Raggett (2014).

$$P_z = 2.56 \times 10^{-6} V^2 K_z G C_D \quad (3.8.1.2.1-1)$$

where:

- P_z = design wind pressure (ksf)
 V = design 3-second gust wind speed, specified in Table 3.8.1.1.2-1 (mph)
 K_z = pressure exposure and elevation coefficient, to be taken equal to $K_z(B)$, $K_z(C)$, or $K_z(D)$ determined using Eqs. 3.8.1.2.1-2, 3.8.1.2.1-3, or 3.8.1.2.1-4, respectively, for Strength III and Service IV load combinations and to be taken as 1.0 for other load combinations

For structure heights less than 33.0 ft, the proximity to the ground surface causes turbulence for which the effect on wind pressure cannot be accurately determined. Therefore, no reduction in the value of K_z is shown in Table C3.8.1.2.1-1 for structure heights less than 33.0 ft.

Strength V and Service I load combinations are based on constant wind speeds that are not functions of the bridge type, bridge height, or the wind exposure category at the location of the bridge. Therefore, the pressure exposure and elevation coefficient, K_z , is taken as 1.0 for these load combinations.

Unlike ASCE 7-10 (2010), which is based on power law wind profiles, these Specifications have always been based on logarithmic wind profiles. Therefore,

G = gust effect factor, determined using a structure-specific study or as specified in Table 3.8.1.2.1-1 for Strength III and Service IV load combinations and 1.0 for other load combinations

C_D = drag coefficient, determined using a structure-specific study or as specified in Table 3.8.1.2.1-2

logarithmic wind profiles were assumed in the development of Eqs. 3.8.1.2.1-2, 3.8.1.2.1-3, and 3.8.1.2.1-4.

The value of K_z at different elevations for different wind exposure categories are shown in Table C3.8.1.2.1-1.

The gust effect factor, G , is a function of the size and dynamic characteristics of the structure including bridge natural frequency and damping. The values specified in Table 3.8.1.2.1-1 are average values for sound barriers and typical bridge structures. For long-span arches, and cable-stayed and suspension bridges, the use of wind tunnel testing to determine a project-specific gust effect factor is warranted.

The 0.85 gust effect factor specified for sound barriers in Table 3.8.1.2.1-1 is consistent with the gust effect factor in ASCE 7-10 (2010) for walls and implies that wind gusts are not likely to engulf the entire barrier. However, the loaded area required to produce the maximum wind load on a sound barrier panel and the panel's vertical supports, if used, is relatively small. A higher gust effect factor may be justifiable because wind gusts may engulf the entire panel.

Table C3.8.1.2.1-1—Pressure Exposure and Elevation Coefficients, K_Z

Structure Height, Z (ft)	Wind Exposure Category B	Wind Exposure Category C	Wind Exposure Category D
≤ 33	0.71	1.00	1.15
40	0.75	1.05	1.20
50	0.81	1.10	1.25
60	0.85	1.14	1.29
70	0.89	1.18	1.32
80	0.92	1.21	1.35
90	0.95	1.24	1.38
100	0.98	1.27	1.41
120	1.03	1.32	1.45
140	1.07	1.36	1.49
160	1.11	1.40	1.52
180	1.15	1.43	1.55
200	1.18	1.46	1.58
250	1.24	1.52	1.63
300	1.30	1.57	1.68

When the wind speed, K_z , and G specified for Strength V and Service I load combinations are substituted in Eq. 3.8.1.2.1-1, the resulting wind pressure on bridge structures, P_z , becomes a multiple of the drag coefficient, C_D , for the structure being considered. The wind pressure in these cases may be calculated using Table C3.8.1.2.1-2.

Table C3.8.1.2.1-2—Wind Pressure on the Bridge Structures for Strength V and Service I Load Combinations

Load Combination	Wind Pressure on the Structure, P_z , for the Specified Wind Speed (ksf)
Strength V	$0.0163C_D$
Service I	$0.0125C_D$

The pressure exposure and elevation coefficient, K_z , for Strength III and Service IV load combinations shall be determined as follows:

$$K_z(B) = \frac{\left[2.5 \ln \left(\frac{Z}{0.9834} \right) + 6.87 \right]^2}{345.6} \quad (3.8.1.2.1-2)$$

$$K_z(C) = \frac{\left[2.5 \ln \left(\frac{Z}{0.0984} \right) + 7.35 \right]^2}{478.4} \quad (3.8.1.2.1-3)$$

$$K_z(D) = \frac{\left[2.5 \ln \left(\frac{Z}{0.0164} \right) + 7.65 \right]^2}{616.1} \quad (3.8.1.2.1-4)$$

where:

$K_z(B)$, $K_z(C)$, and $K_z(D)$ are K_z for wind exposure Category B, C, and D, respectively.

The structure height, Z , used in determining the pressure exposure and elevation coefficient, K_z , shall be taken as:

- For bridge superstructures: the average height of the top of the superstructure above the surrounding ground or water surface.
- For bridge substructures not extending above the elevation of the superstructure: unless otherwise approved by the Owner, the height used in determining the wind pressure on the superstructure.
- For bridge substructures extending above the elevation of the superstructure: unless otherwise approved by the Owner, the height of the top of the substructure.

In the case of a long multi-span bridge with large variation in the ground surface elevation under the bridge, such as a bridge crossing a valley, the structure height, Z , may be varied from a span to span. For each span, the structure height, Z , may be taken as the largest value in the span.

Determining the wind pressure on substructures not extending above the elevation of the superstructure using the structure height used to determine the wind pressure on the superstructure results in slightly conservative values for most substructures. For extremely tall substructures, using a different height, including varying the height used for different segments of the substructure, may be allowed with the approval of the Owner.

Substructures extending above the elevation of the superstructure are typically associated with cable-stayed bridges and suspension bridges. Wind loads on such structures are typically determined using a structure-specific wind tunnel test.

- For ground-mounted sound barriers: The height of the top of the sound barrier above the lower surrounding ground surface.
- For structure- or traffic-barrier-mounted sound barriers: The height of the top of the sound barrier above the low ground or water surface surrounding the support structure.

In no case shall the structure height, Z , used in calculating K_z be taken less than 33.0 ft.

Table 3.8.1.2.1-1—Gust Effect Factor, G

Structure Type	Gust Effect Factor, G
Sound Barriers	0.85
All other structures	1.00

Table 3.8.1.2.1-2—Drag Coefficient, C_D

Component		Drag Coefficient, C_D	
		Windward	Leeward
I-Girder and Box-Girder Bridge Superstructures		1.3	N/A
Trusses, Columns, and Arches	Sharp-Edged Member	2.0	1.0
	Round Member	1.0	0.5
Bridge Substructure		1.6	N/A
Sound Barriers		1.2	N/A

Where the sound barrier is constructed directly atop an embankment, the height of the sound barrier should be measured from the lower ground surface surrounding the embankment.

3.8.1.2.2—Loads on the Superstructure

In the general case of wind analysis, the wind load shall be determined as specified in Article 3.8.1.1 and the wind direction shall be varied. The wind loads shall be taken as the algebraic transverse and longitudinal components of the wind load. The wind direction for design shall be that which produces the maximum force effect in the component under investigation. The transverse and longitudinal components of the wind load shall be applied simultaneously.

3.8.1.2.3—Loads on the Substructure

3.8.1.2.3a—Loads from the Superstructure

The transverse and longitudinal wind load components transmitted by the superstructure to the substructure for various angles of wind directions may be taken as the product of the skew coefficients specified in Table 3.8.1.2.3a-1, the wind pressure calculated using Eq. 3.8.1.2.1-1, and the depth of the bridge. The depth of the bridge shall be as seen in elevation perpendicular to the longitudinal axis of the bridge.

C3.8.1.2.2

The term “columns” in Table 3.8.1.2.1-2 refers to columns in superstructures, such as spandrel columns in arches.

For superstructure components, the wind load on different members should be calculated separately and used in designing the members themselves. For trusses, the wind loads from different members and from the flooring system are transferred to the top and bottom planes of wind bracing and are used in designing the wind bracing system, including the end portals and cross-frames.

C3.8.1.2.3a

The Seventh Edition of *AASHTO Standard Specifications for Highway Bridges* was the first edition to incorporate the wind loads per skew angle of wind (Vincent, 1953). Alternatively, the wind load on the exposed area may be determined using an algebraic summation of transverse and longitudinal components of wind load. However, a wind directionality factor and drag coefficient other than the one specified in Article 3.8.1.2.1 should be considered.

Both components of the wind loads shall be applied as line loads at the mid-depth of the superstructure. In plan, the longitudinal components of wind loads shall be applied as line loads along the longitudinal axis of the superstructure.

The skew angle shall be taken as measured from the perpendicular to the longitudinal axis of the bridge in plan.

The wind direction for design shall be that which produces the maximum force effect in the substructure. The transverse and longitudinal wind load components on the superstructure shall be applied simultaneously.

For girder bridges, the wind pressure may be taken as one line load whose intensity is equal to the product of the wind pressure, skew coefficients, and the depth of the superstructure including the depth of the girders, deck, floor system, railing, and sound barriers, as seen in elevation perpendicular to the longitudinal axis of the bridge. For trusses, columns, and arches, the wind load is the sum of the wind loads on the windward and leeward areas.

The purpose of applying the line load along the longitudinal axis of the bridge in plan is to avoid introducing a moment in the horizontal plane of the superstructure.

Table 3.8.1.2.3a-1—Skew Coefficients for Various Skew Angles of Attack

Skew Angle (degree)	Trusses, Columns, and Arches		Girders	
	Transverse Skew Coefficient	Longitudinal Skew Coefficient	Transverse Skew Coefficient	Longitudinal Skew Coefficient
0	1.000	0.000	1.000	0.000
15	0.933	0.160	0.880	0.120
30	0.867	0.373	0.820	0.240
45	0.627	0.547	0.660	0.320
60	0.320	0.667	0.340	0.380

For usual girder and slab bridges having an individual span length of not more than 150 ft and a maximum height of 33.0 ft above low ground or water level, the following wind load components may be used:

- Transverse: 100 percent of the wind load calculated based on wind direction perpendicular to the longitudinal axis of the bridge.
- Longitudinal: 25 percent of the transverse load.

Both forces shall be applied simultaneously.

3.8.1.2.3b—Loads Applied Directly to the Substructure

The transverse and longitudinal forces to be applied directly to the substructure shall be calculated using the wind pressure determined using Eq. 3.8.1.2.1-1. For wind directions taken skewed to the substructure, the wind pressure shall be resolved into components perpendicular to the end and front elevations of the substructure. The component perpendicular to the end elevation shall act on the exposed substructure area as seen in end elevation, and the component perpendicular to the front elevation shall act on the exposed substructure area as seen in front elevation. The two substructure wind force components shall be applied simultaneously with the wind loads from the superstructure.

C3.8.1.2.3b

When combining the wind forces applied directly to the substructure with the wind forces transmitted to the substructure from the superstructure, all wind forces should correspond to wind blowing from the same direction.

3.8.1.2.4—Wind Loads on Sound Barriers**C3.8.1.2.4**

The wind pressure on ground-mounted or structure-mounted sound barriers shall be determined using Eq. 3.8.1.2.1-1 and assuming the wind direction perpendicular to the plane of the sound barrier.

The sound barrier panels shall be designed assuming the wind pressure is applied as a uniform load to the entire area of the panels.

The vertical support elements (if used), the foundations, and the connection of the panel or the vertical support elements to the foundations or the supporting structure shall be designed for a line load equal in value to the wind pressure multiplied by the sound barrier height. The line load shall be applied at a distance equal to 0.55 times the sound barrier height measured from the bottom of the sound barrier. For determining the location of the line load, the height of the sound barrier shall be taken as the distance from the top of the sound barrier to:

- The ground surface immediately adjacent to the sound barrier for ground-mounted sound barriers.
- The elevation of the sound barrier connection to the supporting structure for structure-mounted sound barriers.

Where the sound barrier is mounted on top of a traffic railing or a retaining wall extending above ground, the magnitude and location of the wind loads transmitted to the base of the supporting traffic railing or retaining wall shall be determined as specified above, assuming that the height of the exposed area is the sum of the height of the sound barrier plus the height of the supporting railing or retaining wall.

The height of the supporting railing or retaining wall to be considered in determining the magnitude and location of the wind load shall be that measured from the top surface of the ground, bridge deck, or roadway pavement to the top of the supporting railing or retaining wall.

3.8.1.3—Wind Load on Live Load: WL **C3.8.1.3**

Wind load on live load shall be represented by an interruptible, moving force of 0.10 klf acting transverse to, and 6.0 ft above, the roadway and shall be transmitted to the structure.

For various angles of wind direction, the transverse and longitudinal components of the wind load on live load may be taken as specified in Table 3.8.1.3-1, with the skew angle measured from the perpendicular to the longitudinal axis of the bridge in plan.

The wind direction for design shall be that which produces the extreme force effect on the component under investigation. The transverse and longitudinal wind load components on the live load shall be applied simultaneously.

The wind pressure is applied as a constant pressure over the entire area of the sound barrier. In reality, the wind speed and, consequently, the wind pressure, increase with the increase in height above the surrounding ground surface. Applying the wind load as a line load at a location above mid-height of the sound barrier better reflects the effect of the uneven pressure distribution.

Where the ground surface elevation is not the same in the front and in the back of a ground-mounted sound barrier, the wind forces will need to be determined for each direction as a separate case of loading. The design of all components must satisfy the demand from both cases.

Historically, the 0.10 klf wind load has been used to determine the wind load on live loads. The value was based on a long row of randomly sequenced passenger cars, commercial vans, and trucks exposed to the maximum wind speed that vehicles can safely travel. The wind load on live load specified herein has not been changed from its value in earlier editions of these Specifications.

This horizontal live load should be applied only to the tributary areas producing a force effect of the same kind, similar to the design lane load.

Table 3.8.1.3-1—Wind Load Components on Live Load

Skew Angle (degrees)	Transverse Component (klf)	Longitudinal Component (klf)
0	0.100	0.000
15	0.088	0.012
30	0.082	0.024
45	0.066	0.032
60	0.034	0.038

For the usual girder and slab bridges having an individual span length of not more than 150 ft and a maximum height of 33.0 ft above low ground or water level, the following wind load components on live load may be used:

- 0.10 klf, transverse
- 0.04 klf, longitudinal

Both forces shall be applied simultaneously.

3.8.2—Vertical Wind Load

The effect of forces tending to overturn structures, unless otherwise determined in Article 3.8.3, shall be calculated as a vertical upward wind load equal to:

- 0.020 ksf for Strength III load combination and
- 0.010 ksf for Service IV load combination

times the width of the deck, including parapets and sidewalks, shall be applied as a line load. This force shall be applied only when the direction of horizontal wind is taken to be perpendicular to the longitudinal axis of the bridge. This line load shall be applied at the windward quarter-point of the deck width in conjunction with the horizontal wind loads specified in Article 3.8.1.

The vertical wind load shall not be applied for load combinations other than Strength III and Service IV.

3.8.3—Wind-Induced Bridge Motions

3.8.3.1—General

The provisions of this Article shall apply to bridges in service and to bridges during construction after the deck and all features affecting their aeroelastic behavior are installed.

Force effects of wind-induced vibrations shall be taken into account in the design of bridges and structural components apt to be wind-sensitive. For the purpose of this Article, the following bridges shall be deemed to be wind-sensitive:

- all bridges with a span-to-depth ratio, and structural components thereof with a length-to-width ratio, exceeding 30.0,

C3.8.2

The intent of this Article is to account for the effect resulting from interruption of the horizontal flow of air by the superstructure. This load is to be applied even to discontinuous bridge decks, such as grid decks. This load may govern where overturning of the bridge is investigated.

For flexible bridges, such as cable-stayed and suspension bridges, the vertical force should be checked as an upward or downward force, whichever may control the design.

C3.8.3.1

Because of the complexity of analyses often necessary for an in-depth evaluation of structural wind-induced vibrations, this Article is intentionally kept to a simple statement. Many bridges, decks, or individual structural components have been shown to be insensitive to wind-induced vibrations if the specified ratios are under 30.0, a somewhat arbitrary value helpful only in identifying likely wind-sensitive cases.

- all cable-supported bridges, and
- all bridges with fundamental vertical or translational periods greater than 1 second.

The potential of wind-induced vibrations of cables, due to any causative mechanism, shall also be considered.

3.8.3.2—Wind-Induced Motions

Wind-induced vibrations due to buffeting, vortex excitation, galloping, flutter, and static divergence of wind-sensitive bridges and wind-sensitive components shall be considered where applicable.

3.8.3.3—Control of Dynamic Responses

For wind-sensitive bridges, peak vertical wind-induced accelerations of the superstructure due to vortex shedding or buffeting should be less than 5 percent of the acceleration of gravity, g , for steady wind

The most common cable vibrations are due to vortex shedding, rain- or wind-induced vibrations, galloping due to the inclination of the cable to the wind, wake galloping, galloping due to aerodynamically unsymmetrical cross-section, excitation from the cable anchorage motion, and buffeting from wind turbulence.

Flexible bridges, such as cable-supported or very long spans of any type, may require special studies based on wind tunnel information. In general, appropriate wind tunnel tests involve simulation of the wind environment local to the bridge site. Details of wind tunnel testing are part of the existing wind tunnel state of the art and are beyond the scope of this commentary.

C3.8.3.2

Excitation due to vortex shedding is the escape of wind-induced vortices behind the member, which tend to excite the component at its fundamental natural frequency in harmonic motion. It is important to keep stresses due to vortex-induced oscillations below the “infinite life” fatigue stress. Methods exist for estimating such stress amplitudes, but they are outside the scope of this commentary.

Tubular components can be protected against vortex-induced oscillation by adding bracing, strakes, or tuned mass dampers, or by attaching horizontal flat plates parallel to the tube axis above and/or below the central third of their span. Such aerodynamic damper plates should lie about one-third tube diameter above or below the tube to allow free passage of wind. The width of the plates may be the diameter of the tube.

Galloping is a high-amplitude oscillation associated with ice-laden cables or long, flexible members that do not have round cross-sections. Cable stays, having circular sections, will gallop when the wind is inclined to the axis of the cable, and when their circumferences are deformed by ice, dropping water, or accumulated debris.

Flexible bridge decks, as in very long spans and some pedestrian bridges, may be prone to wind-induced flutter, a wind-excited oscillation of destructive amplitudes, or, on some occasions, divergence, an irreversible twist under high wind. Analysis methods, including wind tunnel studies leading to adjustments of the deck form, are available for prevention of both flutter and divergence.

C3.8.3.3

Cables in stayed-girder bridges have been successfully stabilized against excessive dynamic responses by attaching mechanical dampers to the bridge at deck level or by cross-tying multiple cable stays.

speeds less than or equal to 30 mph, and should be less than 10 percent of the acceleration of gravity, g , for steady wind speeds greater than 30 mph and less than or equal to 50 mph. Wind-sensitive bridges and wind-sensitive structural components thereof, including cables, shall be designed to be free of fatigue damage due to vortex-induced or galloping oscillations. Bridges shall be designed to be free of divergence, galloping, and catastrophic flutter up to a steady, 10-minute averaged wind speed numerically equal to 0.85 times the design wind speed applicable at the completed bridge at the superstructure elevation.

For the purpose of determining the 10-minute averaged wind speed, the design wind speed applicable for the completed bridge at the superstructure elevation shall be taken equal to $V(K_z)^{1/2}$, for which V and K_z are as defined in Article 3.8.1.2.1.

3.8.4—Site-Specific and Structure-Specific Studies

The requirements of Article 3.8.3 may be satisfied using:

- a site-specific analysis of historical wind data in non-hurricane areas and a site-specific numerical simulation of potential hurricane wind speeds may be used to determine design wind criteria, or
- representative wind tunnel tests using approved procedures may be utilized to determine wind loads and to evaluate aeroelastic stability.

3.9—ICE LOADS: IC

3.9.1—General

This Article refers only to freshwater ice in rivers and lakes; ice loads in seawater should be determined by suitable specialists using site-specific information.

Ice forces on piers shall be determined with regard to site conditions and expected modes of ice action as follows:

- Dynamic pressure due to moving sheets or floes of ice being carried by stream flow, wind, or currents;
- Static pressure due to thermal movements of ice sheets;
- Pressure resulting from hanging dams or jams of ice; and
- Static uplift or vertical load resulting from adhering ice in waters of fluctuating level.

The expected thickness of ice, the direction of its movement, and the height of its action shall be determined by field investigations, review of public records, aerial surveys, or other suitable means.

The 5 percent and 10 percent of the acceleration of gravity, g , for winds below 30 mph and winds between 30 mph and 50 mph, respectively, are typical limits for the motion criteria for pedestrian comfort. They were used successfully in the past in the design of vehicular flexible bridge systems such as cable-stayed and suspension bridges. For higher wind speeds, strength considerations, not motion considerations, govern the design.

The specified 10-minute averaged wind speed, numerically equal to $0.85 V(K_2)^{1/2}$, is that with an approximate mean recurrence interval of 10,000 years. Since catastrophic flutter vibrations take some time to develop, a 10-minute averaged wind speed is used to evaluate the stability of the bridge.

C3.8.4

Wind tunnel testing of bridges and other civil engineering structures is a highly developed technology that may be used to study the wind response characteristics of a structural model or to verify the results of analysis (Simiu, 1976).

C3.9.1

Most of the information for ice loads was taken from Montgomery et al. (1984), which provided background for the clauses on ice loads for the Canadian Standards Association (1988). A useful additional source is Neill (1981).

It is convenient to classify ice forces on piers as dynamic forces and static forces.

Dynamic forces occur when a moving ice floe strikes a bridge pier. The forces imposed by the ice floe on a pier are dependent on the size of the floe, the strength and thickness of the ice, and the geometry of the pier.

The following types of ice failure have been observed (Montgomery et al., 1984):

- Crushing, where the ice fails by local crushing across the width of a pier. The crushed ice is continually cleared from a zone around the pier as the floe moves past.
- Bending, where a vertical reaction component acts on the ice floe impinging on a pier with an inclined nose. This reaction causes the floe to rise up the pier nose, as flexural cracks form.

- Splitting, where a comparatively small floe strikes a pier and is split into smaller parts by stress cracks propagating from the pier.
- Impact, where a small floe is brought to a halt by impinging on the nose of the pier before it has crushed over the full width of the pier, bent or split.
- Buckling, where compressive forces cause a large floe to fail by buckling in front of the nose of a very wide pier.

For bridge piers of usual proportions on larger bodies of water, crushing and bending failures usually control the magnitude of the design dynamic ice force. On smaller streams, which cannot carry large ice floes, impact failure can be the controlling mode.

In all three cases, it is essential to recognize the effects of resonance between the pier and the ice forces. Montgomery et al. (1980) have shown that for a massive pier with a damping coefficient of 20 percent of critical, the maximum dynamic effect is approximately equal to the greatest force, but for lesser damping values there is a considerable amplification.

Montgomery and Lipsett (1980) measure damping of a massive pier at 19 percent of critical, but it is expected that slender piers and individual piles may have damping values of five percent or less.

In the discussion of impact-type ice failure above, the indication is that the floe is “small.” “Small” is extremely difficult to define and is site-specific. Floes up to 75.0 ft long have been observed to fail by splitting when driven by water velocities of 10.0 ft/s (Haynes, 1996).

Static forces may be caused by the thermal expansion of ice in which a pier is embedded or by irregular growth of the ice field. This has typically been observed downstream of a dam, hydroelectric plant, or other channel where ice predominantly forms only on one side of the river or pier.

Ice jams can arch between bridge piers. The break-up ice jam is a more or less cohesionless accumulation of ice fragments (Montgomery et al., 1984).

Hanging dams are created when frazil ice passes under the surface layer of ice and accumulates under the surface ice at the bridge site. The frazil ice comes typically from rapids or waterfalls upstream. The hanging dam can cause a backup of water, which exerts pressure on the pier and can cause scour around or under piers as water flows at an increased velocity.

3.9.2—Dynamic Ice Forces on Piers

3.9.2.1—Effective Ice Strength

In the absence of more precise information, the following values may be used for effective ice crushing strength:

C3.9.2.1

It should be noted that the effective ice strengths given herein are for the purpose of entering into a formula to arrive at forces on piers. Different

- 8.0 ksf, where breakup occurs at melting temperatures and the ice structure is substantially disintegrated;
- 16.0 ksf, where breakup occurs at melting temperatures and the ice structure is somewhat disintegrated;
- 24.0 ksf, where breakup or major ice movement occurs at melting temperatures, but the ice moves in large pieces and is internally sound; and
- 32.0 ksf, where breakup or major ice movement occurs when the ice temperature, averaged over its depth, is measurably below the melting point.

formulas might require different effective ice strengths to arrive at the same result.

As a guide, the 8.0 ksf strength is appropriate for piers where long experience indicates that ice forces are minimal, but some allowance is required for ice effects; the 32.0 ksf strength is considered to be a reasonable upper limit based on the observed history of bridges that have survived ice conditions (Neill, 1981). Effective ice strengths of up to 57.6 ksf have been used in the design of some bridges in Alaska (Haynes, 1996).

The effective ice strength depends mostly on the temperature and grain size of the ice (Montgomery et al., 1984). For example, laboratory-measured compressive strengths at 32°F vary from about 60.0 ksf for grain sizes of 0.04 in. to 27.0 ksf for grain sizes of 0.2 in., and at 23°F ice strengths are approximately double the values given. Thus, the effective ice strengths given herein are not necessarily representative of laboratory tests or actual ice strengths, and, in fact, are on the order of one-half of observed values (Neill, 1981).

The compressive strength of the ice depends upon temperature, but the tensile strength is not sensitive to temperature. Because much ice failure is the result of splitting or tensile failure in bending, and because grain sizes, cracks, and other imperfections vary in the field, only crude approximations of ice strengths can be made. Thus, temperature is not a consideration for setting effective ice strengths in these Specifications.

Some of the most severe ice runs in the United States occur during a rapid January thaw, when the air temperature is about 50°F, but the average ice temperature can still be below 32°F because of an insulating snow cover (Haynes, 1996).

3.9.2.2—Crushing and Flexing

The horizontal force, F , resulting from the pressure of moving ice shall be taken as:

- If $\frac{w}{t} \leq 6.0$, then:

F = lesser of either F_c or, when ice failure by flexure is considered applicable as described herein, F_b , and

- If $\frac{w}{t} > 6.0$, then:

$$F = F_c$$

in which:

$$F_c = C_a p t w \quad (3.9.2.2-1)$$

$$F_b = C_n p t^2 \quad (3.9.2.2-2)$$

C3.9.2.2

The expression of F_c is based on field measurements of forces on two bridge piers in Alberta (Lipsett and Gerard, 1980). See also Huiskamp (1983), with a value of C_a proposed by Afanas'ev et al. (1971) and verified by Neill (1976).

The expression for F_b is taken from Lipsett and Gerard (1980).

$w/t = 6.0$ is a rough estimate of the upper limit of w/t at which ice that has failed by bending will be washed around the pier.

It is assumed that the force on the pier is governed by the crushing or bending strength of the ice, and thus there is not a term in Eqs. 3.9.2.2-1 or 3.9.2.2-2 relating to velocity of the ice. The interaction between an ice floe and a pier depends on the size and strength of the floe and how squarely it strikes the pier. It has been reported that an ice floe 200 ft in size will usually fail by crushing if it hits a pier squarely. If a floe 100 ft in size does not hit the pier squarely, it will usually impact the pier and rotate around the pier and pass downstream with only little local crushing.

$$C_a = (5t/w + 1)^{0.5} \quad (3.9.2.2-3)$$

$$C_n = \frac{0.5}{\tan(\alpha - 15)} \quad (3.9.2.2-4)$$

where:

- t = thickness of ice (ft)
- α = inclination of the nose to the vertical (degrees)
- p = effective ice crushing strength, as specified in Article 3.9.2.1 (ksf)
- w = pier width at level of ice action (ft)
- F_c = horizontal ice force caused by ice floes that fail by crushing over the full width of the pier (kip)
- F_b = horizontal ice force caused by ice floes that fail by flexure as they ride up the inclined pier nose (kip)
- C_a = coefficient accounting for the effect of the pier width/ice thickness ratio where the floe fails by crushing
- C_n = coefficient accounting for the inclination of the pier nose with respect to the vertical

where $\alpha \leq 15$ degrees, ice failure by flexure shall not be considered to be a possible ice failure mode for the purpose of calculating the horizontal force, F , in which case F shall be taken as F_c .

Although no account is taken of the shape of the nose of the pier, laboratory tests at the U.S. Army Corps of Engineers' Cold Regions Research and Engineering Laboratory (CRREL) have shown the bullet-shaped pier nose can reduce ice forces the most compared to other types of geometry. Pointed angular noses, as shown in Figure C3.9.2.4.1-1, have been found to cause lateral vibrations of the pier without reducing the streamwise force. CRREL has measured lateral or torsional vibrations on the pointed nose Yukon River Bridge piers. The long-term ramifications of these vibrations are not known at this time (Haynes, 1996).

Ice thickness is the greatest unknown in the determination of ice forces on piers. Equations can be used for estimating ice thickness. The design should be based on the extreme, not average, ice thickness. The elevation on the pier where the design force shall be applied is important for calculating the overturning moments. Because ice stage increases during an ice run, relying on local knowledge of the maximum stage is vital to proper design (Haynes, 1995). For the purpose of design, the preferred method to establish the thickness of ice, t , is to base it on measurements of maximum thicknesses, taken over a period of several years, at the potential bridge sites.

Where observations over a long period of time are not available, an empirical method based on Neill (1981) is suggested as follows:

$$t = 0.083\alpha\sqrt{S_f} \quad (C3.9.2.2-1)$$

where:

- α = coefficient for local conditions, normally less than 1.0
- S_f = freezing index, being the algebraic sum, $\Sigma(32 - T)$, summed from the date of freeze-up to the date of interest, in degree days
- T = mean daily air temperature (degrees F)

Assuming that temperature records are available, the maximum recorded value of S_f can be determined.

One possible method of determining α is by simple calibration in which, through the course of a single winter, the ice thickness can be measured at various times and plotted against $\sqrt{S_f}$.

As a guide, Neill (1981) indicates the following values for α :

windy lakes without snow	0.8
average lake with snow	0.5–0.7
average river with snow	0.4–0.5
sheltered small river with snow	0.2–0.4

Due to its good insulating characteristics, snow has a significant effect on ice growth. Williams (1963) has shown that a snow cover greater than 6.0 in. in thickness has the effect of reducing α by as much as 50 percent.

Neill does not define “average,” and it has been noted by Gerard and Stanely (1992) that deep snow can produce snow-ice, thus offsetting the benefits of snow insulation.

Large lakes take longer to cool down, which leads to a later freeze-up date. This results in fewer degree-days of freezing and, hence, smaller ice thicknesses.

The remaining decision is to establish the appropriate elevation of the ice force to be applied to the pier. The elevation required is that at break-up, not at the mean winter level. Neill (1981) suggests several methods of determining ice elevations, but the most common method in general use is probably to rely on local knowledge and examination of the river banks to determine the extent of damage by ice, such as the marking or removal of trees.

3.9.2.3—Small Streams

On small streams not conducive to the formation of large ice floes, consideration may be given to reducing the forces, F_b and F_c , determined in accordance with Article 3.9.2.2, but under no circumstances shall the forces be reduced by more than 50 percent.

C3.9.2.3

CAN/CSA-S6-88 has an expression for ice forces in small streams, for which a theory is given by Montgomery et al. (1984). It is considered insufficiently verified to be included herein.

On small streams, with a width of less than 300 ft at the mean water level, dynamic ice forces, as determined in Article 3.9.2.2, may be reduced in accordance with Table C3.9.2.3-1. Another important factor that determines the ice floe size are the type of features in the river upstream of the site. Islands, dams, and bridge piers can break ice into small floes.

where:

A = plan area of the largest ice floe (ft²)
 r = radius of pier nose (ft)

Table C3.9.2.3-1—Reduction Factor K_1 for Small Streams

A/r^2	Reduction Factor, K_1
1,000	1.0
500	0.9
200	0.7
100	0.6
50	0.5

The rationale for the reduction factor, K_1 , is that the bridge may be struck only by small ice floes with insufficient momentum to cause failure of the floe.

3.9.2.4—Combination of Longitudinal and Transverse Forces

3.9.2.4.1—Piers Parallel to Flow

The force, F , determined as specified in Articles 3.9.2.2 and 3.9.2.3, shall be taken to act along the longitudinal axis of the pier if the ice movement has only one direction and the pier is approximately aligned

C3.9.2.4.1

It would be unrealistic to expect the ice force to be exactly parallel to the pier, so a minimum lateral component of 15 percent of the longitudinal force is specified.

with that direction. In this case, two design cases shall be investigated as follows:

- A longitudinal force equal to F shall be combined with a transverse force of $0.15F$, or
- A longitudinal force of $0.5F$ shall be combined with a transverse force of F_t .

The transverse force, F_t , shall be taken as:

$$F_t = \frac{F}{2 \tan(\beta/2 + \theta_f)} \quad (3.9.2.4.1-1)$$

where:

- β = nose angle in a horizontal plane for a round nose taken as 100 (degrees)
- θ_f = friction angle between ice and pier nose (degrees)

Both the longitudinal and transverse forces shall be assumed to act at the pier nose.

The expression for F_t comes from Montgomery et al. (1984), and is explained in Figure C3.9.2.4.1-1 taken from the same source.

Figure C3.9.2.4.1-1—Transverse Ice Force Where a Floe Fails over a Portion of a Pier

3.9.2.4.2—Piers Skewed to Flow

Where the longitudinal axis of a pier is not parallel to the principal direction of ice action, or where the direction of ice action may shift, the total force on the pier shall be determined on the basis of the projected pier width and resolved into components. Under such conditions, forces transverse to the longitudinal axis of the pier shall be taken to be at least 20 percent of the total force.

3.9.2.5—Slender and Flexible Piers

Slender and flexible piers shall not be used in regions where ice forces are significant, unless advice on ice/structure interaction has been obtained from an ice specialist. This provision also applies to slender and flexible components of piers, including piles that come into contact with water-borne ice.

3.9.3—Static Ice Loads on Piers

Ice pressures on piers frozen into ice sheets shall be investigated where the ice sheets are subject to significant thermal movements relative to the pier where the growth of shore ice is on one side only or in other situations that may produce substantial unbalanced forces on the pier.

C3.9.2.4.2

The provisions for piers skewed to flow are taken from CAN/CSA-S6-88 (1988).

C3.9.2.5

It has been shown by Montgomery, et al. (1980) and others that flexible piers and pier components may experience considerable amplification of the ice forces as a result of resonant ice/structure interaction at low levels of structural damping. In this case, the provisions of Article 3.9.5 may be inadequate for vertical forces on piers.

C3.9.3

Little guidance is available for predicting static ice loads on piers. Under normal circumstances, the effects of static ice forces on piers may be strain-limited, but expert advice should be sought if there is reason for concern. Static ice forces due to thermal expansion of ice are discussed in Haynes (1995). Ice force can be reduced by several mitigating factors that usually apply. For example, ice does not act simultaneously over the full length of the pier. Thermal stresses relax in time and prevent high stresses over the full ice thickness. A snow cover on the

3.9.4—Hanging Dams and Ice Jams

The frazil accumulation in a hanging dam may be taken to exert a pressure of 0.2 to 2.0 ksf as it moves by the pier. An ice jam may be taken to exert a pressure of 0.02 to 0.20 ksf.

3.9.5—Vertical Forces Due to Ice Adhesion

The vertical force, in kips, on a bridge pier due to rapid water level fluctuation shall be taken as:

For a circular pier:

$$F_v = 80.0t^2 \left(0.35 + \frac{0.03R}{t^{0.75}} \right) \quad (3.9.5-1)$$

For an oblong pier:

$$F_v = 0.2t^{1.25}L + 80.0t^2 \left(0.35 + \frac{0.03R}{t^{0.75}} \right) \quad (3.9.5-2)$$

where:

- t = ice thickness (ft)
- R = radius of circular pier (ft); or radius of half circles at ends of an oblong pier (ft); or radius of a circle that circumscribes each end of an oblong pier of which the ends are not circular in plan at water level (ft)
- L = perimeter of pier, excluding half circles at ends of oblong pier (ft)

ice insulates the ice and reduces the thermal stresses, and ice usually acts simultaneously on both sides of the pier surrounded by the ice so that the resultant force is considerably less than the larger directional force, i.e., force on one side of the pier. Article C3.9.1 contains additional discussion.

C3.9.4

The theory behind the ice pressures given for hanging dams can be found in Montgomery, et al. (1984). The wide spread of pressures quoted reflects both the variability of the ice and the lack of firm information on the subject.

C3.9.5

Eq. 3.9.5-1 was derived by considering the failure of a semi-infinite, wedge-shaped ice sheet on an elastic foundation under vertical load applied at its apex. For a single ice wedge, the maximum vertical force, P , can be evaluated from the expression (Nevel, 1972).

$$P = \frac{\tan\left(\frac{\delta}{2}\right) \sigma_T t^2}{3} \left[1.05 + 2\left(\frac{a}{\ell}\right) + 0.5\left(\frac{a}{\ell}\right)^3 \right] \quad (C3.9.5-1)$$

in which:

$$\begin{aligned} \ell &= \left(\frac{Et^3}{12\gamma} \right)^{0.25} \\ &= 21.0t^{0.75} \end{aligned} \quad (C3.9.5-2)$$

where:

- σ_T = tensile strength of ice (ksf)
- t = maximum thickness of ice (ft)
- δ = angle of the truncated wedge (degrees)
- a = truncated distance, which is assumed to be equal to the radius of a circular pier (ft)
- ℓ = characteristic length calculated from the expression (ft)
- E = Young's modulus for ice (ksf)
- γ = unit weight of water (kcf)

To obtain Eq. 3.9.5-1, the vertical force is summed for four wedges, each with a truncated angle of 90 degrees. It is assumed that the tensile strength of ice is 0.84 times an effective crushing strength of 23 ksf and that the ratio of the truncated distance to the characteristic length, a/ℓ , is less than 0.6.

Eq. 3.9.5-2 is the sum of two expressions:

- Eq. 3.9.5-1, which accounts for the vertical ice forces acting on the half circles at the ends of an oblong pier, and
- An expression that calculates the vertical ice forces on the straight walls of the pier.

3.9.6—Ice Accretion and Snow Loads on Superstructures

Generally snow loads, other than those caused by an avalanche, need not be considered. However, Owners in areas where unique accumulations of snow and/or ice are possible should specify appropriate loads for that condition.

Loads due to icing of the superstructure by freezing rain shall be specified if local conditions so warrant.

The expression for calculating the vertical ice forces on the long straight walls of the pier was derived by considering a semi-infinite, rectangular ice sheet on an elastic foundation under a uniformly distributed edge load. The force required to fail the ice sheet, F , can be expressed as $F = 0.236 \sigma_T t^2 / \ell$ (Montgomery et al., 1984).

Eqs. 3.9.5-1 and 3.9.5-2 are based on the conservative assumption that ice adheres around the full perimeter of the pier cross-section. They neglect creep and are, therefore, conservative for water level fluctuations occurring over more than a few minutes. However, they are also based on the nonconservative assumption that failure occurs on the formation of the first crack.

Some issues surrounding ice forces have been reported in Zabilansky (1996).

C3.9.6

The following discussion of snow loads is taken from Ritter (1990).

Snow loads should be considered where a bridge is located in an area of potentially heavy snowfall. This can occur at high elevations in mountainous areas with large seasonal accumulations. Snow loads are normally negligible in areas of the United States that are below 2,000 ft elevation and east of longitude 105°W, or below 1,000 ft elevation and west of longitude 105°W. In other areas of the country, snow loads as large as 0.7 ksf may be encountered in mountainous locations.

The effects of snow are assumed to be offset by an accompanying decrease in vehicle live load. This assumption is valid for most structures, but is not realistic in areas where snowfall is significant. When prolonged winter closure of a road makes snow removal impossible, the magnitude of snow loads may exceed those from vehicular live loads. Loads also may be notable where plowed snow is stockpiled or otherwise allowed to accumulate. The applicability and magnitude of snow loads are left to the Designer's judgment.

Snow loads vary from year to year and depend on the depth and density of snowpack. The depth used for design should be based on a mean recurrence interval or the maximum recorded depth. Density is based on the degree of compaction. The lightest accumulation is produced by fresh snow falling at cold temperatures. Density increases when the snowpack is subjected to freeze-thaw cycles or rain. Probable densities for several snowpack conditions are indicated in Table C3.9.6-1 (ASCE, 1980).

Table C3.9.6-1—Snow Density

Condition of Snowpack	Probable Density (kef)
Freshly Fallen	0.006
Accumulated	0.019
Compacted	0.031
Rain or Snow	0.031

Estimated snow load can be determined from historical records or other reliable data. General information on ground snow loads is available from the National Weather Service, from state and local agencies, and ASCE (1988). Snow loads in mountain areas are subject to extreme variations. The extent of these loads should be determined on the basis of local experience or records, instead of on generalized information.

The effect of snow loads on a bridge structure is influenced by the pattern of snow accumulation. Windblown snow drifts may produce unbalanced loads considerably greater than those produced from uniformly distributed loads. Drifting is influenced by the terrain, structure shape, and other features that cause changes in the general wind flow. Bridge components, such as railings, can serve to contain drifting snow and cause large accumulations to develop.

3.10—EARTHQUAKE EFFECTS: EQ

3.10.1—General

Bridges shall be designed to have a low probability of collapse but may suffer significant damage and disruption to service over a 75-year period. Partial or complete replacement may be required. Higher levels of performance may be used with the authorization of the Bridge Owner. When seismic isolation is used, the design shall be in accordance with the *AASHTO Guide Specifications for Seismic Isolation Design*, unless otherwise specified by the Owner.

Earthquake loads shall be taken to be horizontal force effects determined in accordance with the provisions of Article 4.7.4 on the basis of the spectral accelerations specified in Article 3.10.4, the period of the structure, the equivalent weight of the superstructure, and adjusted by the response modification factor, R , specified in Article 3.10.7.1.

The provisions herein shall apply to bridges of conventional construction. The Owner shall specify and/or approve appropriate provisions for nonconventional construction. Unless otherwise specified by the Owner, these provisions need not be applied to completely buried structures.

Seismic effects for box culverts and buried structures need not be considered, except where they cross active faults.

The potential for soil liquefaction and its consequences, seismic-induced slope movements, and seismic earth pressures shall be considered.

C3.10.1

The design earthquake motions and forces specified in these provisions are based on a limit state of incipient collapse at a targeted risk of approximately 1.5 percent over 75 years. This is not an actual collapse probability, but rather the probability of reaching an Extreme Event limit-state given the application of the minimum required provisions provided herein. Bridges that are designed and detailed in accordance with these provisions may suffer damage, but should have low probability of collapse due to seismically-induced ground shaking.

The principles used for the development of these Specifications are:

- Small-to-moderate earthquakes should be resisted within the elastic range of the structural components without significant damage;
- Realistic seismic ground motion intensities and forces should be used in the design procedures; and
- Exposure to shaking from large earthquakes should not cause collapse of all or part of the bridge. Where possible, damage that does occur should be readily detectable and accessible for inspection and repair.

Bridge Owners may choose to mandate higher levels of performance for special bridges. See the *AASHTO Guidelines for Performance-Based Seismic Design of Highway Bridges* for more information.

Earthquake loads are given by the product of the spectral acceleration corresponding to the period of the structure and the equivalent weight of the superstructure. The equivalent weight is a function of the actual weight and bridge configuration and is automatically included in both the single-mode and multimode methods of analysis specified in Article 4.7.4. Design and detailing provisions for bridges to minimize their susceptibility to damage from earthquakes are contained in Sections 3, 4, 5, 6, 7, 10, and 11. A flow chart summarizing these provisions is presented in Appendix A3.

Conventional bridges include those with slab, beam, box girder, or truss superstructures, and single- or multiple-column piers, wall-type piers, or pile-bent substructures. In addition, conventional bridges are founded on shallow or piled footings, or shafts. Substructures for conventional bridges are also listed in Table 3.10.7.1-1. Nonconventional bridges include bridges with cable-stayed/cable-suspended superstructures, bridges with truss towers or hollow piers for substructures, and arch bridges.

These Specifications are considered to be force-based, wherein a bridge is designed to have adequate strength (capacity) to resist earthquake forces (demands). In recent years, there has been a trend away from force-based procedures to those that are displacement-based, wherein a bridge is designed to have adequate displacement capacity to accommodate earthquake demands. Displacement-based procedures are believed to more reliably identify the limit states that cause damage leading to collapse, and in some cases, produce more efficient designs against collapse. It is recommended that the displacement capacity of bridges designed in accordance with these Specifications be checked using a displacement-based procedure, particularly those bridges in high seismic zones. The *AASHTO Guide Specifications for LRFD Seismic Bridge Design* (AASHTO, 2023), are displacement-based.

3.10.2—Seismic Hazard

The seismic hazard at a bridge site shall be characterized by the acceleration response spectrum for the site, including the effects of the relevant site class.

The acceleration spectrum shall be determined using either the General Procedure specified in Article 3.10.2.1 or the Site-Specific Procedure specified in Article 3.10.2.2. The Site-Specific Procedure can involve a site-specific seismic hazard analysis, a site-specific ground response analysis or both, as described in these Specifications.

A site-specific seismic hazard analysis shall be conducted if any one of the following conditions exist:

- There has been a recent discovery of a new active fault or seismic source zone that could affect the potential level of ground shaking at a site;
- Long-period (e.g., > 10 s) ground motions are required for the seismic design of the bridge;

C3.10.2

A site-specific seismic hazard analysis involves determination of ground motions by conducting either a probabilistic seismic hazard analysis (PSHA) or a deterministic seismic hazard analysis (DSHA). A site-specific ground response analysis involves determining the detailed effects of local geology and soil conditions at a given site on ground surface motions using numerical modeling methods. Requirements for site-specific seismic hazard and site-specific ground response analyses are discussed in Article 3.10.2.2.

- Long-duration earthquakes are expected in the region; or
- The importance of the bridge is such that a lower risk target should be considered.

A site-specific ground response analysis shall be conducted if any one of the following conditions exist:

- The site is classified as Site Class F (Article 3.10.3.1), or
- The site has a shear wave velocity, V_s , profile or site condition that warrants special consideration.

Performance of site-specific seismic hazard and seismic ground response analyses requires Owner's approval.

Special consideration is required if a site is located within 9.5 mi (15 km) of the surface projection of a known active fault capable of producing $M_w 7$ or larger events, or 6.25 mi (10 km) of the surface projection of a known active fault capable of producing $M_w 6$ or larger events. Ground motions for such sites, whether based on the General Procedure or Site-Specific Procedures, shall be adjusted for near-fault effects. If time histories of ground acceleration are used to characterize the level of ground shaking for the site, they shall be determined in accordance with Article 4.7.4.3.4b. Time histories for near-fault sites, as defined above, shall include near-fault directionality and velocity pulse considerations.

3.10.2.1—General Procedure

The General Procedure shall use the design response spectrum specified in Article 3.10.4. The effect of site class on the seismic hazard shall be as specified in Article 3.10.3.

Ground motions resulting from large seismic events located within 6 to 10 mi of a site can alter spectral accelerations at certain periods from impulsive and directionality effects not recorded at more distant sites. Past observations have found that these effects can be very destructive if not appropriately considered. These effects depend on earthquake magnitude. Procedures used to account for near-fault effects include empirical adjustments to the shape of the response spectrum or including the near-fault effect in the PSHA. See discussions in Huang et al. (2008), Shahi and Baker (2011), and Watson-Lamprey (2018) for methods to assess near-fault effects. The requirement for including near-fault effects can be waived if: (1) the estimated slip rate of the fault is less than 0.04 in. (1 mm) per year; or (2) the surface projection resulting in the near-fault site determination is based on depths of 6.25 mi. (10 km) or greater.

C3.10.2.1

Previous versions of these Specifications used a uniform seismic hazard approach to develop the design ground motions, while the current Specifications use a risk-targeted approach. A uniform hazard approach relates elastic spectral response to ground motions representing a single probability of exceedance over a given time frame (or return period), whereas a risk-targeted approach relates elastic spectral response to the probability of attaining a specific limit state, considering all ground motion return periods. The risk-targeted approach has the advantage of addressing differing seismic hazard rates of change across the country and is analogous to applying calibrated load factors in the strength and service limit-states. The hazard curves for the risk-targeted approach are based on the USGS 2018 Seismic Hazard Model. Similar to previous work, spectral acceleration values correspond to 5 percent critical damping. The targeted risk for incipient column collapse is set to 1.5 percent in 75 years, using a notional fragility function.

A notional fragility (probabilistic relationship between limit state and ground motion) is used for the calculation of risk. The notional fragility curve utilized has a lognormal distribution with a log-standard

deviation of 0.6, and a probability of exceedance at the design ground motion of 5 percent. It represents a condition of incipient collapse of an Ordinary Bridge column, which does not necessarily indicate that the point of actual structure collapse has been reached, only that the capacity that can be reasonably relied upon has been exhausted. Further unquantified capacity may exist, although lateral resistance may be diminished. This should be kept in mind when considering the target value of 1.5 percent of reaching this condition in the bridge's 75-year life. This is not an actual collapse probability, but rather the probability of reaching an Extreme Event limit-state.

The use of a 75-year interval to characterize this probability is an arbitrary convenience and does not imply that all bridges are thought to have a useful life of 75 years.

In lieu of using the AASHTO-USGS Seismic Design Ground Motion Database, values for the spectral accelerations may be derived from approved state ground motion maps. To be acceptable, the development of state maps should conform to the following:

- The targeted risk should be equal or lower than those described herein.
- Ground motion maps should be based on a detailed analysis demonstrated to lead to a quantification of ground motion, at a regional scale, that is as accurate or more so, as is achieved in the AASHTO-USGS Seismic Design Database. The analysis should include: characterization of seismic sources and ground motion that incorporates current scientific knowledge; incorporation of uncertainty in seismic source models, ground motion models, and parameter values used in the analysis; and detailed documentation of map development.

Detailed peer review should be undertaken as deemed appropriate by the Owner. The peer review process should include individuals with demonstrated scientific knowledge and experience in the development of risk-targeted ground motion evaluations.

3.10.2.2—Site-Specific Procedure

A site-specific seismic hazard analysis and/or a site-specific ground response analysis to develop risk-targeted design response spectra of earthquake ground motions shall be performed when required by Article 3.10.2 and may be performed for any site subject to the Owner's approval.

The objective of the site-specific seismic hazard analysis should be to generate risk-targeted acceleration response spectra with target parameters consistent with or lower than those used to develop the accelerations described in Article 3.10.2. This analysis should involve establishing:

- the contributing seismic sources;

C3.10.2.2

The intent in conducting a site-specific seismic hazard analysis and/or a site-specific ground response analysis is to develop ground motions that are more accurate for the local and regional seismic and site conditions than can be determined from the AASHTO-USGS Seismic Design Ground Motion Database or, in the case of Site Class F, are not covered by the AASHTO-USGS Seismic Design Ground Motion Database. The site-specific seismic hazard analysis is coupled with a notional fragility function, using an iterative integration procedure with the desired target risk criteria, to develop the site-specific, risk-targeted design response spectrum. NEHRP 21.2.1 contains a description of this process (FEMA, 2020).

- an upper-bound earthquake magnitude for each source zone;
- median attenuation relations for acceleration response spectral values and their associated standard deviations;
- a magnitude-recurrence relation for each source zone; and
- a fault-rupture-length relation for each contributing fault.

Uncertainties in source modeling and parameter values shall be taken into consideration. Detailed documentation of the risk-adjusted seismic hazard analysis is required and shall be peer reviewed.

Where analyses to determine site-specific ground response are required by Article 3.10.3.1 for Site Class F soils, or to address unique characteristics of the shear wave velocity profile at a site, the influence of the local soil conditions shall be determined based on site-specific geotechnical investigations and dynamic site response analyses. The site-specific ground response analysis may require peer review, as determined by the Owner.

For sites located within 6 to 10 mi of an active surface or a shallow fault, as depicted in the USGS Active Fault Map, studies shall be considered to quantify near-fault effects on ground motions to determine if these could significantly influence the bridge response.

A deterministic spectrum may be utilized in regions having known active faults if the deterministic spectrum is no less than two-thirds of the risk-targeted ground motion spectrum obtained using the General Procedure for periods equal to or less than $2T_F$ of the spectrum, where T_F is the bridge fundamental period. Where use of a deterministic spectrum is appropriate, the spectrum shall be either:

- the envelope of a median spectra calculated for characteristic maximum magnitude earthquakes on known active faults; or
- defined for each fault, and, in the absence of a clearly controlling spectra, each spectrum should be used.

Site-specific seismic hazard studies should be comprehensive and incorporate current scientific interpretations at a local and regional scale. Because there are typically scientifically credible alternatives for models and parameter values used to characterize seismic sources and ground-motion attenuation, it is important to incorporate these uncertainties formally in a site-specific seismic hazard analysis. Examples of these uncertainties include seismic source location, extent, and geometry; maximum earthquake magnitude; earthquake recurrence rate; and ground-motion model aleatory variability and epistemic uncertainty.

Site-specific ground response studies should account for the variation in the soil shear wave velocity between the ground surface and the depth at which ground motions are assigned to the numerical model, as well as a range of earthquake records consistent with seismic sources that could cause earthquake shaking at the site. See Article 3.4.3.2 of the *AASHTO Guide Specifications for LRFD Seismic Bridge Design* (AASHTO, 2023) for requirements of site-specific ground response analyses.

There are four options for conducting site-specific hazard and site-specific ground response analyses. Three of the options involve use of ground motions from a PSHA; the fourth involves a DSHA. These options will generally require Owner approval, and they may require an independent peer review:

1. **Site-Specific PSHA:** A site-specific PSHA is conducted using a site-specific seismic hazard model. The reasons for conducting the site-specific PSHA could be a change in seismic conditions near the project site (e.g., a newly discovered active fault), desire to include near-fault or other effects in the hazard analysis, or importance of the project to the Owner, among other reasons. This approach would be used to define the risk-targeted design response spectrum at the ground surface for all site classes except Site Class F. Sites meeting requirements of Site Class F require a site-specific ground response analysis.
2. **Site-Specific PSHA with Site-Specific Ground Response Analysis:** The same approach described in Option 1 is used except that the risk-targeted design response spectrum is defined for Site Class BC or at the elevation of a significant stiffness contrast in the soil profile. The risk-targeted spectrum for the BC Site Class (or stiffness contrast) is used to select earthquake records, and then ground response analysis is conducted using any one of a number of one-dimensional (1-D) or two-dimensional (2-D) computer programs to account for local site effects. If the site is located near an active fault, the appropriate number of selected earthquake records should include a velocity pulse to represent likely near-fault effects.
3. **General Procedure with Site-Specific Ground Response Analysis:** The AASHTO-USGS Seismic

Design Ground Motion Database is used to define the risk-targeted hazard spectrum for Site Class BC or at a significant stiffness contrast, and then the ground response analysis is conducted following Option 2.

4. Deterministic Seismic Hazard Analysis (DSHA): Article 3.4.3.1 of these Specifications includes the option of conducting a DSHA. If the Designer determines that a DSHA is required, and with the Owner's concurrence, procedures given in Article 3.4.3.1 can be used to determine the ground motions at the ground surface. The minimum value of the resulting DSHA ground motions should be no less than two-thirds of the risk-targeted General Procedure defined above.

Near-fault effects on horizontal response spectra include:

- Higher ground motions due to the proximity of the active fault;
- Directivity effects that increase ground motions for periods greater than 0.5 s if the fault rupture propagates toward the site; and
- Directionality effects that increase ground motions for periods greater than 0.5 s in the direction normal (perpendicular) to the strike of the fault.

If the active fault is included and appropriately modeled in the development of the AASHTO-USGS Seismic Design Ground Motion Database, then the first effect above is already included in the determination of the risk-targeted ground motion. The second and third effects are not included in the AASHTO-USGS Seismic Design Ground Motion Database. These effects are generally most significant for periods longer than 0.5 s and normally would be evaluated only for Recovery or Critical bridges having natural periods of vibration longer than 0.5 s. Further discussions of the second and third effects are contained in Somerville et al. (1997), Shahi and Baker (2011), Donahue et al. (2019), and Caltrans (2019).

The fault-normal component of near-field ($D < 6$ or 10 mi depending on magnitude) motion may contain relatively long-duration velocity pulses which can cause severe nonlinear structural response, predictable only through nonlinear time-history analyses. For this case, the recorded near-field horizontal components of motion need to be transformed into principal components before modifying them to be response-spectrum-compatible.

The ratio of vertical-to-horizontal ground motions increases for short-period motions in the near-fault environment.

Where response spectra at the ground surface are determined from a site-specific seismic hazard or site-specific ground response study, the spectra shall not be lower than two-thirds of the response spectra determined using the General Procedure.

3.10.3—Site Effects

The site classes specified herein shall be used in the General Procedure for developing the design ground motions specified in Article 3.10.4.

3.10.3.1—Site Class Definitions

A site shall be classified as A through F in accordance with the site class definitions in Table 3.10.3.1-1. Sites shall be classified by their stiffness as determined by the time-averaged shear wave velocity in the upper 100 ft ($\bar{v}_s$).

Where shear wave velocity is not measured, appropriate generalized correlations between shear wave velocity and Standard Penetration Test (SPT) blow counts, Cone Penetration Test (CPT) tip resistance, shear strengths, or other geotechnical parameters can be used to obtain an estimated shear wave velocity profile subject to the provisions of this Article. Site class types shall be assigned in accordance with the definitions provide in Table 3.10.3.1-1.

Where measured shear wave velocity data are not available, site class based on estimated $\bar{v}_s$ shall be derived using each of $\bar{v}_s$, $\bar{v}_s/1.33$, and $1.3\bar{v}_s$ when correlation models are used to derive shear wave velocities. Where correlations derived for specific local regions can be demonstrated to have greater accuracy, factors less than 1.3 can be used if approved by the Owner. If the different average velocities result in different site classes per Table 3.10.3.1-1, the most critical of the site classes for ground motion analysis at each period shall be determined by the geotechnical engineer.

C3.10.3

The behavior of a bridge during an earthquake is strongly related to the soil conditions at the site. Soils can amplify ground motions in the underlying rock, sometimes by factors of two or more. Conversely, very soft soils may *de-amplify* ground motions due to non-linear effects. The extent of this modification of ground motions is dependent on the profile of soil types at the site and the intensity of shaking in the rock below. Sites are classified by type and profile for the purpose of defining the overall seismic hazard, which is quantified as the product of the soil amplification and the intensity of shaking in the underlying rock.

C3.10.3.1

Various correlations exist between shear wave velocity and field measurements from the SPT blow count, the CPT end resistance, or equations that relate shear wave velocity to voids ratio, effective overburden pressure, over-consolidation ratio, and plasticity. While these correlations provide reasonable estimates of $\bar{v}_s$ for most cases, they include a significant amount of uncertainty, as evidenced by large standard deviations associated with the median shear wave estimates. If these correlations are used instead of direct measurements of $\bar{v}_s$, then the uncertainties of the $\bar{v}_s$ determination must be included in the site class evaluation. Since uncertainties can result in either higher or lower $\bar{v}_s$ values compared to the measurement, both cases need to be considered when using the correlation to estimate the site class. Increasing and decreasing the estimated $\bar{v}_s$ by a factor of 1.3 is intended to address this uncertainty.

Methods for determining $\bar{v}_s$ are discussed in Section 10 of these Specifications. Even when high-quality $\bar{v}_s$ profiles are established by field measurements, the uncertainty in these measurements can result in a ± 10 percent variation in $\bar{v}_s$. This variation should also be considered when making the site class determination.

Table 3.10.3.1-1—Site Class Definitions

Site Class	Soil Type and Profile	$\bar{v}_s$ Calculated or Estimated
A	Hard rock	$\bar{v}_s > 5,000$ ft/s
B	Medium hard rock	$3,000 \text{ ft/s} < \bar{v}_s \leq 5,000 \text{ ft/s}$
B/C	Soft rock	$2,100 \text{ ft/s} < \bar{v}_s \leq 3,000 \text{ ft/s}$
C	Very dense sand or hard clay	$1,450 \text{ ft/s} < \bar{v}_s \leq 2,100 \text{ ft/s}$
C/D	Dense sand or very stiff clay	$1,000 \text{ ft/s} < \bar{v}_s \leq 1,450 \text{ ft/s}$
D	Medium dense sand or stiff clay	$700 \text{ ft/s} < \bar{v}_s \leq 1,000 \text{ ft/s}$
D/E	Loose sand or medium stiff clay	$500 \text{ ft/s} < \bar{v}_s \leq 700 \text{ ft/s}$
E	Very loose sand or soft clay	$\bar{v}_s \leq 500 \text{ ft/s}$
F	Soils requiring site-specific ground response evaluations, such as: • Peats or highly organic clays ($H > 10.0$ ft of peat or highly organic clay where H = thickness of soil) • Very high plasticity clays ($H > 25.0$ ft with $PI > 75$) • Very thick, soft/medium stiff clays ($H > 120$ ft)	

Exceptions: Where the soil properties are not known in sufficient detail to determine the site class, a site investigation shall be undertaken sufficient to determine the site class. Site Classes E or F should not be assumed unless the Owner or those having jurisdiction determines that Site Classes E or F could be present at the site or in the event that Site Classes E or F are established by geotechnical data.

where:

$\bar{v}_s$ = average shear wave velocity for the upper 100 ft of the soil profile

Table C3.10.3.1-1—Steps for Site Classification

Step	Description
1	Check for the three categories of Site Class F in Table 3.10.3.1-1 requiring site-specific evaluation. If the site corresponds to any of these categories, classify the site as Site Class F and conduct a site-specific evaluation.
2	Check for existence of a soft layer with total thickness > 10 ft, where soft layer is defined by $s_u < 0.5$ ksf, $w > 40$ percent, and $PI > 20$. If these criteria are met, classify site as Site Class E.
3	Categorize the site into one of the site classes in Table 3.10.3.1-1 using the following method to calculate: • $\bar{v}_s$ for the top 100 ft ($\bar{v}_s$ method) To make these calculations, the soil profile is subdivided into n distinct soil and rock layers, and in the methods below the symbol i refers to any one of these layers from 1 to n. The average $\bar{v}_s$ for the top 100 ft is determined as: $\bar{v}_s = \frac{\sum_{i=1}^n d_i}{\sum_{i=1}^n \frac{d_i}{v_{si}}}$ where: $\sum_{i=1}^n d_i = 100 \text{ ft}$ v_{si} = shear wave velocity in ft/s of a layer d_i = thickness of a layer between 0 and 100 ft

3.10.4—Seismic Hazard Characterization

3.10.4.1—Design Response Spectrum

The 5 percent-damped, risk targeted-design response spectrum shall be constructed using response spectral accelerations taken from the AASHTO-USGS Seismic Design Ground Motion Database as described in this Article. The ground motion database provides risk-targeted design acceleration coefficients, S_a , at 22 different periods as follows: 0 seconds (A_s), 0.01, 0.02, 0.03, 0.05, 0.075, 0.1, 0.15, 0.2, 0.25, 0.3, 0.4, 0.5, 0.75, 1.0, 1.5, 2.0, 3.0, 4.0, 5.0, 7.5, and 10 s.

The risk-targeted design response spectrum shall be constructed directly using these values, with linear interpolation between the provided values. For periods greater than 10 seconds, the design acceleration coefficients shall be determined by a site-specific, risk-targeted seismic hazard analysis.

Risk-targeted design acceleration coefficients are provided for each site class defined in Article 3.10.3.1.

3.10.5—Operational Classification

For the purpose of Article 3.10, the Owner or those having jurisdiction shall classify the bridge into one of three operational categories as follows:

- Critical bridges,
- Recovery bridges, or
- Ordinary bridges.

The basis of classification shall include social/survival and security/defense requirements. In classifying a bridge, consideration should be given to possible future changes in conditions and requirements.

3.10.6—Seismic Performance Zones

Each bridge shall be assigned to one of the four seismic zones in accordance with Table 3.10.6-1 using the value of S_{DI} as determined below:

C3.10.4.1

The AASHTO-USGS Seismic Design Ground Motion Database (AASHTO, 2023) can be found at <https://doi.org/10.5066/F7NK3C76>.

For periods exceeding about 4 s, it has been observed that in certain seismic environments spectral displacements tend to a constant value which implies that the acceleration spectrum becomes inversely proportional to T^2 at these periods. Where structural behavior at long periods is of consequence, consideration should be given to developing site-specific seismic hazard motions.

In contrast to previous editions, the effects of site class have been directly included in the ground motion database and do not require further modification for use in the general method.

An earthquake may excite several modes of vibration in a bridge and, therefore, the elastic response coefficient should be found for each relevant mode.

The discussion of the single-mode method in the commentary to Article 4.7.4.3.2 illustrates the relationship between period, S_a , and quasi-static seismic forces, $p_e(x)$. The structure is analyzed for these seismic forces in the single-mode method. In the multimode method, the structure is analyzed for several sets of seismic forces, each corresponding to the period and mode shape of one of the modes of vibration, and the results are combined using acceptable methods, such as the Complete Quadratic Combination (CQC) method as required in Article 4.7.4.3.3. S_a applies to weight, not mass.

C3.10.5

Recovery bridges are generally those that should, as a minimum, be open to emergency vehicles and for security/defense purposes immediately after the design earthquake. However, some bridges must remain open to all traffic after the design earthquake and be usable by emergency vehicles and for security/defense purposes immediately after an earthquake larger than the design event. These bridges should be regarded as critical structures. Bridges not classified as Critical or Recovery are classified as Ordinary.

These definitions apply specifically to the operational classification for seismic design and should not be confused with the operational importance of Article 1.3.5.

C3.10.6

These seismic zones reflect the variation in seismic risk across the country and are used to permit different requirements for methods of analysis, minimum support lengths, column design details, and foundation and abutment design procedures.

S_{DI} = 90 percent of the maximum value of the product, TS_a , for periods from 1 to 2 s for sites with $\bar{v}_s > 1,450$ ft/s and for periods 1 to 5 s for sites with $\bar{v}_s \leq 1,450$ ft/s, but not less than 100 percent of the value of S_a at 1 s where T is the period of vibration for each value of S_a .

The criteria for determining S_{DI} use the maximum value of the product TS_a over the period range of interest to effectively identify the period at which the peak value of response spectral velocity occurs. This allows for variations in the response spectrum that do not follow the previously assumed $1/T$ proportionality representing a constant velocity portion of the design response spectrum. The use of 90 percent for the product TS_a effectively does two things: 1) develops a $1/T$ proportional spectral acceleration curve that is an envelope of the “mapped” response spectrum of Article 3.4.1 in the period range of interest and 2) takes 90 percent of that curve to recognize that many points on the “mapped” curve lie below the envelope. The use of 100 percent of the mapped 1-s spectral acceleration accounts for sites where the peak spectral acceleration is at or near 1-second. The use of either 2 s or 5 s for determining the peak spectral velocity recognizes that the peak typically occurs at less than 5 s and to avoid very long period ground motions that may not be reliable (Building Seismic Safety Council, 2020) The approach provides a reasonably conservative estimate of S_{DI} for the purpose of establishing the Seismic Zone.

Table 3.10.6-1—Seismic Zones

S_{DI}	Seismic Zone
$S_{DI} \leq 0.15$	1
$0.15 < S_{DI} \leq 0.30$	2
$0.30 < S_{DI} \leq 0.50$	3
$0.50 < S_{DI}$	4

3.10.7—Response Modification Factors

3.10.7.1—General

To apply the response modification factors specified herein, the structural details shall satisfy the provisions of Articles 5.10.2.2 and 5.11.

Except as noted herein, seismic design force effects for substructures and the connections between parts of structures, listed in Table 3.10.7.1-2, shall be determined by dividing the force effects resulting from elastic analysis by the appropriate response modification factor, R , as specified in Tables 3.10.7.1-1 and 3.10.7.1-2, respectively.

As an alternative to the use of the R -factors, specified in Table 3.10.7.1-2 for connections, monolithic joints between structural members and/or structures, such as a column-to-footing connection, may be designed to transmit the maximum force effects that can be developed by the inelastic hinging of the column or multicolumn bent they connect as specified in Article 3.10.9.4.3.

If an inelastic time history method of analysis is used, the response modification factor, R , shall be taken as 1.0 for all substructure and connections.

C3.10.7.1

These Specifications recognize that it is uneconomical to design a bridge to resist large earthquakes elastically. Columns are assumed to deform inelastically where seismic forces exceed their design level, which is established by dividing the elastically computed force effects by the appropriate R -factor.

R -factors for connections are smaller than those for substructure members in order to preserve the integrity of the bridge under these extreme loads. For expansion joints within the superstructure and connections between the superstructure and abutment, the application of the R -factor results in force effect magnification. Connections that transfer forces from one part of a structure to another include, but are not limited to, fixed bearings, expansion bearings with either restrainers, STUs, or dampers, and shear keys. For one-directional bearings, these R -factors are used in the restrained direction only. In general, forces determined on the basis of plastic hinging will be less than those given by using Table 3.10.7.1-2, resulting in a more economical design.

Table 3.10.7.1-1—Response Modification Factors—Substructures

Substructure	Operational Category		
	Critical	Recovery	Ordinary
Wall-type piers—larger dimension	1.5	1.5	2.0
Reinforced concrete pile bents			
• Vertical piles only	1.5	2.0	3.0
• With batter piles	1.5	1.5	2.0
Single columns	1.5	2.0	3.0
Steel or composite steel and concrete pile bents			
• Vertical pile only	1.5	3.5	5.0
• With batter piles	1.5	2.0	3.0
Multiple column bents	1.5	3.5	5.0

Table 3.10.7.1-2 Response Modification Factors—Connections

Connection	All Operational Categories
Superstructure to abutment	0.8
Expansion joints within a span of the superstructure	0.8
Columns, piers, or pile bents to cap beam or superstructure	1.0
Columns or piers to foundations	1.0

3.10.7.2—Application

Seismic loads shall be assumed to act in any lateral direction.

The appropriate *R*-factor shall be used for both orthogonal axes of the substructure.

A wall-type concrete pier may be analyzed as a single column in the weak direction if all the provisions for columns, as specified in Section 5, are satisfied.

C3.10.7.2

Usually the orthogonal axes will be the longitudinal and transverse axes of the bridge. In the case of a curved bridge, the longitudinal axis may be the chord joining the two abutments.

Wall-type piers may be treated as wide columns in the strong direction, provided the appropriate *R*-factor in this direction is used.

3.10.8—Combination of Seismic Force Effects

The elastic seismic force effects on each of the principal axes of a component resulting from analyses in the two perpendicular directions shall be combined to form two load cases as follows:

- 100 percent of the absolute value of the force effects in one of the perpendicular directions combined with 30 percent of the absolute value of the force effects in the second perpendicular direction, and
- 100 percent of the absolute value of the force effects in the second perpendicular direction combined with 30 percent of the absolute value of the force effects in the first perpendicular direction.

Where foundation and/or column connection forces are determined from plastic hinging of the columns specified in Article 3.10.9.4.3, the resulting force effects may be determined without consideration of combined load cases specified herein. For the purpose of this provision, “column connection forces” shall be taken as the shear and moment, computed on the basis of plastic hinging. The axial load shall be taken as that resulting from the appropriate load combination with the axial load, if any, associated with plastic hinging taken as *EQ*. If a pier is designed as a column as specified in Article 3.10.7.2, this exception shall be taken to apply for

C3.10.8

The exception to these load combinations indicated at the end of this Section should also apply to bridges in Zone 2 where foundation forces are determined from plastic hinging of the columns.

the weak direction of the pier where force effects resulting from plastic hinging are used; the combination load cases specified must be used for the strong direction of the pier.

3.10.9—Calculation of Design Forces

3.10.9.1—General

For single-span bridges, regardless of seismic zone, the minimum design connection force effect in the restrained direction between the superstructure and the substructure shall not be less than the product of the acceleration coefficient, A_s , and the tributary permanent load.

Minimum support lengths at expansion bearings of multispan bridges shall either comply with Article 4.7.4.4 or STUs, and dampers shall be provided.

3.10.9.2—Seismic Zone 1

For bridges in Zone 1 where the acceleration coefficient, A_s , is less than 0.05, the horizontal design connection force in the restrained directions shall not be less than 0.15 times the vertical reaction due to the tributary permanent load and the tributary live loads assumed to exist during an earthquake.

For all other sites in Zone 1, the horizontal design connection force in the restrained directions shall not be less than 0.25 times the vertical reaction due to the tributary permanent load and the tributary live loads assumed to exist during an earthquake.

For each uninterrupted segment of a superstructure, the tributary permanent load at the line of fixed bearings, used to determine the longitudinal connection design force, shall be the total permanent load of the segment.

If each bearing supporting an uninterrupted segment or simply supported span is restrained in the transverse

C3.10.9.1

This Article refers to superstructure effects carried into substructure. Abutments on multispan bridges, but not single-span bridges, and retaining walls are subject to acceleration-augmented soil pressures as specified in Articles 3.11.4 and 11.6.5. Wingwalls on single-span structures are not fully covered at this time, and the Engineer should use judgment in this area.

C3.10.9.2

These provisions arise because, as specified in Article 4.7.4, seismic analysis for bridges in Zone 1 is not generally required. The minimum connection design forces of this Article are used in lieu of determining such forces through rigorous analysis. The division of Zone 1 at an acceleration coefficient, A_s , of 0.05 recognizes that, in parts of the country with very low seismicity, seismic forces on connections are relatively small. However as outlined below, the intent of this Article is to prevent connections from becoming unintended weak links in the seismic lateral load path. Accordingly, the minimum connection forces specified in this Article are intended to be sufficiently conservative to prevent premature failure and are not intended to precisely reflect the expected dynamic seismic forces. See Article C3.10.7.1 for a description of typical elements considered to be connections, and note that a connection, as considered in this Article, may be an element that simply restrains a member and may not physically connect to that member, such as transverse shear keys. Additionally, anchorage detailing for connections should be extended far enough into the adjacent member to ensure that premature or unintentional local failure is prevented. Similarly, the design of a girder support pedestal should consider the connection forces specified in this Article, since failure of a pedestal located above the pier cap could potentially lead to loss of span support.

In Zone 1, the prevention of superstructure collapse due to unseating of spans is the primary objective behind the provisions for minimum connection forces in restrained directions, as covered by this Article, and for minimum support lengths for unrestrained directions (e.g. expansion bearings), as covered by Article 4.7.4.4. The minimum connection forces specified in this Article are not intended to be minimum design forces for the bridge, because the main elements of the bridge in Zone 1 should generally be capable of resisting the expected lateral seismic forces, by virtue of satisfying the nonseismic

direction, the tributary permanent load used to determine the connection design force shall be the permanent load reaction at that bearing.

Each elastomeric bearing and its connection to the masonry and sole plates shall be designed to resist the horizontal seismic design forces transmitted through the bearing. For all bridges in Seismic Zone 1 and all single-span bridges, these seismic shear forces shall not be less than the connection force specified herein.

design requirements. However, this presumed structural resistance is predicated on providing sufficient integrity and connectivity within the structure to mobilize the lateral resistance of the main structural elements (e.g. columns, pier caps, superstructure, abutments, and foundations).

Accordingly, the design forces for connections need only be considered for those elements that directly prevent loss of span support or prevent system instability. Connections that fall into this category include, but are not limited to, those elements restraining the superstructure at in-span hinges and at substructure support locations. Other connections in this category include connections between substructure elements if failure of such connections could lead to loss of span support. For example, failure of the connections between steel piles and a precast concrete bent cap could lead to loss of support for both the cap and superstructure and, therefore, such a connection should meet the requirements of this Article.

If the minimum connection forces are deemed unreasonably large, the design may be completed using the requirements of a higher seismic zone. The minimum requirements of this Article require adequate connection strength for restrained directions and adequate support length in unrestrained directions. In many cases, it is feasible, conservative, and economical to provide both sufficient connection force capacity and support length, and both should be considered. In situations where load sharing of connections may be uncertain, adequate support length, in addition to the required connection force capacity, should be considered. An example is the case of bearings that may not take up load equally, thus leading to the possibility of “unzipping” of the lateral restraint elements. In cases where support length is needed in the transverse direction, the designer is cautioned that the minimum support length equations for N were developed empirically considering longitudinal response. Thus, adequate support in the transverse direction should be based on engineering judgment to prevent loss of superstructure support.

If each bearing supporting a continuous segment or simply supported span is an elastomeric bearing, there may be no fully restrained directions due to the flexibility of the bearings. However, the forces transmitted through these bearings should be determined in accordance with this Article and Article 14.6.3. If positive connection capable of transferring the minimum force is not provided, then the minimum support length requirements for expansion bearings of Article 4.7.4.4 should be followed. For this Article, friction is not considered a positive connection due to uncertainty resulting from vertical effects.

The magnitude of live load assumed to exist at the time of the earthquake should be consistent with the value of γ_{eq} used in conjunction with Table 3.4.1-1.

The designer is cautioned that in some geographic locations for certain site conditions, spectral accelerations may exceed the minimum connection forces of this Article. Typically, such a condition may occur for

3.10.9.3—Seismic Zone 2

Structures in Seismic Zone 2 shall be analyzed according to the minimum requirements specified in Articles 4.7.4.1 and 4.7.4.3.

Except for foundations, seismic design forces for all components, including pile bents and retaining walls, shall be determined by dividing the elastic seismic forces, obtained from Article 3.10.8, by the appropriate response modification factor, R , specified in Table 3.10.7.1-1.

Seismic design forces for foundations, other than pile bents and retaining walls, shall be determined by dividing elastic seismic forces, obtained from Article 3.10.8, by one-half of the response modification factor, R , from Table 3.10.7.1-1, for the substructure component to which it is attached. The value of $R/2$ shall not be taken as less than 1.0.

Where a group load other than Extreme Event I, specified in Table 3.4.1-1, governs the design of columns, the possibility that seismic forces transferred to the foundations may be larger than those calculated using the procedure specified above, due to possible overstrength of the columns, shall be considered.

3.10.9.4—Seismic Zones 3 and 4

3.10.9.4.1—General

Structures in Seismic Zones 3 and 4 shall be analyzed according to the minimum requirements specified in Articles 4.7.4.1 and 4.7.4.3.

The design forces of each component shall be taken as the lesser of those determined using:

- the provisions of Article 3.10.9.4.2; or
- the provisions of Article 3.10.9.4.3,

for all components of a column, column bent and its foundation and connections.

structures with fundamental vibration periods at or near the short-period plateau of the response spectra (e.g. stiff structures, such as those with wall piers). When this occurs, the Designer should consider the effects due to potential connection failure and should consider providing the minimum support lengths of Article 4.7.4.4.

C3.10.9.3

This Article specifies the design forces for foundations which include the footings, pile caps, and piles. The design forces are essentially twice the seismic design forces of the columns. This will generally be conservative and was adopted to simplify the design procedure for bridges in Zone 2. However, if seismic forces do not govern the design of columns and piers there is a possibility that during an earthquake the foundations will be subjected to forces larger than the design forces. For example, this may occur due to unintended column overstrengths which may exceed the capacity of the foundations. An estimate of this effect may be found by using a resistance factor, ϕ , of 1.3 for reinforced concrete columns and 1.25 for structural steel columns. It is also possible that even in cases when seismic loads govern the column design, the columns may have insufficient shear strength to enable a ductile flexural mechanism to develop, but instead allow a brittle shear failure to occur. Again, this situation is due to potential overstrength in the flexural capacity of columns and could possibly be prevented by arbitrarily increasing the column design shear by the overstrength factor cited above.

Conservatism in the design, and in some cases underdesign, of foundations and columns in Zone 2 based on the simplified procedure of this Article has been widely debated (Gajer and Wagh, 1994). In light of the above discussion, it is recommended that for Critical or Recovery bridges in Zone 2 consideration should be given to the use of the forces specified in Article 3.10.9.4.3f for foundations in Zone 3 and Zone 4. Ultimate soil and pile strengths are to be used with the specified foundation seismic design forces.

C3.10.9.4.1

In general, the design forces resulting from an R -factor and inelastic hinging analysis will be less than those from an elastic analysis. However, in the case of architecturally oversized column(s), the forces from an inelastic hinging analysis may exceed the elastic forces in which case the elastic forces may be used for that column, column bent and its connections and foundations.

3.10.9.4.2—Modified Design Forces

Modified design forces shall be determined as specified in Article 3.10.9.3, except that for foundations the R -factor shall be taken as 1.0.

3.10.9.4.3—Inelastic Hinging Forces

3.10.9.4.3a—General

Where inelastic hinging is invoked as a basis for seismic design, the force effects resulting from plastic hinging at the top and/or bottom of the column shall be calculated after the preliminary design of the columns has been completed utilizing the modified design forces specified in Article 3.10.9.4.2 as the seismic loads. The consequential forces resulting from plastic hinging shall then be used for determining design forces for most components as identified herein. The procedures for calculating these consequential forces for single column and pier supports and bents with two or more columns shall be taken as specified in the following Articles.

Inelastic hinges shall be ascertained to form before any other failure due to overstress or instability in the structure and/or in the foundation. Inelastic hinges shall only be permitted at locations in columns where they can be readily inspected and/or repaired. Inelastic flexural resistance of substructure components shall be determined in accordance with the provisions of Sections 5 and 6.

Superstructure and substructure components and their connections to columns shall also be designed to resist a lateral shear force from the column determined from the factored inelastic flexural resistance of the column using the resistance factors specified herein.

These consequential shear forces, calculated on the basis of inelastic hinging, may be taken as the extreme seismic forces that the bridge is capable of developing.

3.10.9.4.3b—Single Columns and Piers

Force effects shall be determined for the two principal axes of a column and in the weak direction of a pier or bent as follows:

- Step 1—Determine the column overstrength moment resistance. Use a resistance factor, ϕ , of 1.3 for reinforced concrete columns and 1.25 for structural steel columns. For both materials, the applied axial load in the column shall be determined using Extreme Event Load Combination I, with the maximum elastic column axial load from the seismic forces determined in accordance with Article 3.10.8, taken as EQ .
- Step 2—Using the column overstrength moment resistance, calculate the corresponding column shear force. For flared columns, this calculation shall be performed using the overstrength resistances at both the top and bottom of the flare in conjunction with the

C3.10.9.4.2

Acceptable damage is restricted to inelastic hinges in the columns. The foundations should, therefore, remain in their elastic range. Hence the value for the R -factor is taken as 1.0.

C3.10.9.4.3a

By virtue of Article 3.10.9.4.2, alternative conservative design forces are specified if plastic hinging is not invoked as a basis for seismic design.

In most cases, the maximum force effects on the foundation will be limited by the extreme horizontal force that a column is capable of developing. In these circumstances, the use of a lower force, lower than that specified in Article 3.10.9.4.2, is justified and should result in a more economic foundation design.

See also Appendix B3.

C3.10.9.4.3b

The use of the factors 1.3 and 1.25 corresponds to the normal use of a resistance factor for reinforced concrete. In this case, it provides an increase in resistance, i.e., overstrength. Thus, the term “overstrength moment resistance” denotes a factor resistance in the parlance of these Specifications.

appropriate column height. If the foundation of a column is significantly below ground level, consideration should be given to the possibility of the plastic hinge forming above the foundation. If this can occur, the column length between plastic hinges shall be used to calculate the column shear force.

Force effects corresponding to a single column hinging shall be taken as:

- **Axial Forces**—Those determined using Extreme Event Load Combination I, with the unreduced maximum and minimum seismic axial load of Article 3.10.8, taken as EQ .
- **Moments**—Those calculated in Step 1.
- **Shear Force**—That calculated in Step 2.

3.10.9.4.3c—Piers with Two or More Columns

C3.10.9.4.3c

Force effects for bents with two or more columns shall be determined both in the plane of the bent and perpendicular to the plane of the bent. Perpendicular to the plane of the bent, the forces shall be determined as for single columns in Article 3.10.9.4.3b. In the plane of the bent, the forces shall be calculated as follows:

- Step 1—Determine the column overstrength moment resistances. Use a resistance factor, ϕ , of 1.3 for reinforced concrete columns and 1.25 for structural steel columns. For both materials the initial axial load should be determined using the Extreme Event Load Combination I with $EQ = 0$.
- Step 2—Using the column overstrength moment resistance, calculate the corresponding column shear forces. Sum the column shears of the bent to determine the maximum shear force for the pier. If a partial-height wall exists between the columns, the effective column height should be taken from the top of the wall. For flared columns and foundations below ground level, the provisions of Article 3.10.9.4.3b shall apply. For pile bents, the length of pile above the mud line shall be used to calculate the shear force.
- Step 3—Apply the bent shear force to the center of mass of the superstructure above the pier and determine the axial forces in the columns due to overturning when the column overstrength moment resistances are developed.
- Step 4—Using these column axial forces as EQ in the Extreme Event Load Combination I, determine revised column overstrength moment resistance. With the revised overstrength moment resistances, calculate the column shear forces and the maximum shear force for the bent. If the maximum shear force for the bent is not within ten percent of the value previously determined, use this maximum bent shear force and return to Step 3.

See Article C3.10.9.4.3b.

The forces in the individual columns in the plane of a bent corresponding to column hinging shall be taken as:

- Axial Forces—The maximum and minimum axial loads determined using Extreme Event Load Combination I, with the axial load determined from the final iteration of Step 3, taken as EQ and treated as plus and minus.
- Moments—The column overstrength moment resistances corresponding to the maximum compressive axial load specified above.
- Shear Force—The shear force corresponding to the column overstrength moment resistances specified above, noting the provisions in Step 2 above.

3.10.9.4.3d—Column and Pile Bent Design Forces

Design forces for columns and pile bents shall be taken as a consistent set of the lesser of the forces determined as specified in Article 3.10.9.4.1, applied as follows:

- Axial Forces—The maximum and minimum design forces determined using Extreme Event Load Combination I with either the elastic design values determined in Article 3.10.8, taken as EQ , or the values corresponding to plastic hinging of the column taken as EQ .
- Moments—The modified design moments determined for Extreme Event Limit State Load Combination I.
- Shear Force—The lesser of either the elastic design value determined for Extreme Event Limit State Load Combination I with the seismic loads combined as specified in Article 3.10.8 and using an R -factor of 1 for the column, or the value corresponding to plastic hinging of the column.

3.10.9.4.3e—Pier Design Forces

The design forces shall be those determined for Extreme Event Limit State Load Combination I, except where the pier is designed as a column in its weak direction. If the pier is designed as a column, the design forces in the weak direction shall be as specified in Article 3.10.9.4.3d and all the design requirements for columns, as specified in Section 5, shall apply. When the forces due to plastic hinging are used in the weak direction, the combination of forces, specified in Article 3.10.8, shall be applied to determine the elastic moment which is then reduced by the appropriate R -factor.

3.10.9.4.3f—Foundation Design Forces

The design forces for foundations including footings, pile caps and piles may be taken as either those forces determined for the Extreme Event Load Combination I, with the seismic loads combined as specified in Article 3.10.8, or the forces at the bottom of the columns corresponding to column plastic hinging as determined in Article 3.10.8.

C3.10.9.4.3d

The design axial forces which control both the flexural design of the column and the shear design requirements are either the maximum or minimum of the unreduced design forces or the values corresponding to plastic hinging of the columns. In most cases, the values of axial load and shear corresponding to plastic hinging of the columns will be lower than the unreduced design forces. The design shear forces are specified so that the possibility of a shear failure in the column is minimized.

When an inelastic hinging analysis is performed, these moments and shear forces are the maximum forces that can develop and, therefore, the directional load combinations of Article 3.10.8 do not apply.

C3.10.9.4.3e

The design forces for piers specified in Article 3.10.9.4.3e are based on the assumption that a pier has low ductility capacity and no redundancy. As a result, a low R -factor of 2 is used in determining the reduced design forces, and it is expected that only a small amount of inelastic deformation will occur in the response of a pier when subjected to the forces of the design earthquake. If a pier is designed as a column in its weak direction, then both the design forces and, more importantly, the design requirements of Articles 3.10.9.4.3d and Section 5 are applicable.

C3.10.9.4.3f

The foundation design forces specified are consistent with the design philosophy of minimizing damage that would not be readily detectable. The recommended design forces are the maximum forces that can be transmitted to the footing by plastic hinging of the column. The alternate design forces are the elastic design forces. It should be noted that these may be considerably greater than the

When the columns of a bent have a common footing, the final force distribution at the base of the columns in Step 4 of Article 3.10.9.4.3c may be used for the design of the footing in the plane of the bent. This force distribution produces lower shear forces and moments on the footing because one exterior column may be in tension and the other in compression due to the seismic overturning moment. This effectively increases the ultimate moments and shear forces on one column and reduces them on the other.

3.10.9.5—Longitudinal Restrainers

Friction shall not be considered to be an effective restrainer.

Restrainers shall be designed for a force calculated as the acceleration coefficient, A_s , times the permanent load of the lighter of the two adjoining spans or parts of the structure.

If the restrainer is at a point where relative displacement of the sections of superstructure is designed to occur during seismic motions, sufficient slack shall be allowed in the restrainer so that the restrainer does not start to act until the design displacement is exceeded.

Where a restrainer is to be provided at columns or piers, the restrainer of each span may be attached to the column or pier rather than to interconnecting adjacent spans.

In lieu of restrainers, STUs may be used and designed for either the elastic force calculated in Article 4.7 or the maximum force effects generated by inelastic hinging of the substructure as specified in Article 3.10.7.1.

3.10.9.6—Hold-Down Devices

For Seismic Zones 2, 3, and 4, hold-down devices shall be provided at supports and at hinges in continuous structures where the vertical seismic force due to the longitudinal seismic load opposes and exceeds 50 percent, but is less than 100 percent, of the reaction due to permanent loads. In this case, the net uplift force for the design of the hold-down device shall be taken as ten percent of the reaction due to permanent loads that would be exerted if the span were simply supported.

If the vertical seismic forces result in net uplift, the hold-down device shall be designed to resist the larger of either:

- 120 percent of the difference between the vertical seismic force and the reaction due to permanent loads, or
- Ten percent of the reaction due to permanent loads.

3.10.10—Requirements for Temporary Bridges and Stage Construction

Any bridge or partially constructed bridge that is expected to be temporary for more than 5 years shall be designed using the requirements for permanent structures and shall not use the provisions of this Article.

recommended design forces, although where architectural considerations govern the design of a column, the alternate elastic design forces may be less than the forces resulting from column plastic hinging.

See also the second paragraph of C3.10.9.4.3d.

C3.10.10

The option to use a reduced response coefficient and a reduced ground acceleration coefficient reflects the limited exposure period for a temporary bridge.

The requirement that an earthquake shall not cause collapse of all or part of a bridge, as stated in Article 3.10.1, shall apply to temporary bridges expected to carry traffic. It shall also apply to those bridges that are constructed in stages and expected to carry traffic and/or pass over routes that carry traffic. The design response spectral acceleration coefficient may be reduced by a factor of not more than 2 in order to calculate the component elastic forces and displacements. Response and acceleration coefficients for construction sites that are close to active faults shall be the subject of special study. The response modification factors given in Article 3.10.7 may be increased by a factor of not more than 1.5 in order to calculate the design forces. This factor shall not be applied to connections as defined in Table 3.10.7.1-2.

The minimum support length provisions of Article 4.7.4.4 shall apply to all temporary bridges and staged construction.

3.11—EARTH PRESSURE: *EH*, *ES*, *LS*, AND *DR*

3.11.1—General

Earth pressure shall be considered as a function of the:

- type and unit weight of earth,
- water content,
- soil creep characteristics,
- degree of compaction,
- location of groundwater table,
- earth-structure interaction,
- amount of surcharge,
- earthquake effects,
- back slope angle, and
- wall inclination.

Silt and lean clay shall not be used for backfill unless suitable design procedures are followed and construction control measures are incorporated in the construction documents to account for their presence. Consideration shall be given for the development of pore water pressure within the soil mass in accordance with Article 3.11.3. Appropriate drainage provisions shall be provided to

C3.11.1

Walls that can tolerate little or no movement should be designed for at-rest earth pressure. Walls which can move away from the soil mass should be designed for pressures between active and at-rest conditions, depending on the magnitude of the tolerable movements. Movement required to reach the minimum active pressure or the maximum passive pressure is a function of the wall height and the soil type. Some typical values of these mobilizing movements, relative to wall height, are given in Table C3.11.1-1, where:

Δ = movement of top of wall required to reach minimum active or maximum passive pressure by tilting or lateral translation (ft)

H = height of wall (ft)

Table C3.11.1-1—Approximate Values of Relative Movements Required to Reach Active or Passive Earth Pressure Conditions (Clough and Duncan, 1991)

Type of Backfill	Values of Δ/H	
	Active	Passive
Dense sand	0.001	0.01
Medium dense sand	0.002	0.02
Loose sand	0.004	0.04
Compacted silt	0.002	0.02
Compacted lean clay	0.010	0.05
Compacted fat clay	0.010	0.05

The evaluation of the stress induced by cohesive soils is highly uncertain due to their sensitivity to shrink-swell, wet-dry and degree of saturation. Tension cracks can form, which considerably alter the assumptions for the estimation of stress. Extreme caution is advised in the determination of lateral earth pressures assuming the most unfavorable conditions.

prevent hydrostatic and seepage forces from developing behind the wall in accordance with the provisions in Section 11. In no case shall highly plastic clay be used for backfill.

3.11.2—Compaction

Where activity by mechanical compaction equipment is anticipated within a distance of one-half the height of the wall, taken as the difference in elevation between the point where finished grade intersects the back of the wall and the base of the wall, the effect of additional earth pressure that may be induced by compaction shall be taken into account.

3.11.3—Presence of Water

If the retained earth is not allowed to drain, the effect of hydrostatic water pressure shall be added to that of earth pressure.

In cases where water is expected to pond behind a wall, the wall shall be designed to withstand the hydrostatic water pressure plus the earth pressure.

Submerged unit weights of the soil shall be used to determine the lateral earth pressure below the groundwater table.

If possible, cohesive or other fine-grained soils should be avoided as backfill.

For walls retaining cohesive materials, the effects of soil creep should be taken into consideration in estimating the design earth pressures. Evaluation of soil creep is complex and requires duplication in the laboratory of the stress conditions in the field as discussed by Mitchell (1976).

Under stress conditions close to the minimum active or maximum passive earth pressures, cohesive soils indicated in Table C3.11.1-1 creep continually, and the movements shown produce active or passive pressures only temporarily. If there is no further movement, active pressures will increase with time, approaching the at-rest pressure, and passive pressures will decrease with time, approaching values on the order of 40 percent of the maximum short-term value. A conservative assumption to account for unknowns would be to use the at-rest pressure based on the residual strength of the soil.

C3.11.2

Compaction-induced earth pressures may be estimated using the procedures described by Clough and Duncan (1991). The heavier the equipment used to compact the backfill, and the closer it operates to the wall, the larger are the compaction-induced pressures. The magnitude of the earth pressures exerted on a wall by compacted backfill can be minimized by using only small rollers or hand compactors within a distance of one-half wall height from the back of the wall. For MSE structures, compaction stresses are already included in the design model and specified compaction procedures.

C3.11.3

The effect of additional pressure caused by groundwater is shown in Figure C3.11.3-1.

Figure C3.11.3-1—Effect of Groundwater Table

If the groundwater levels differ on opposite sides of the wall, the effects of seepage on wall stability and the potential for piping shall be considered. Pore water pressures shall be added to the effective horizontal stresses in determining total lateral earth pressures on the wall.

3.11.4—Effect of Earthquake

The effects of wall inertia and probable amplification of active earth pressure and/or mobilization of passive earth masses by earthquake shall be considered.

3.11.5—Earth Pressure: *EH*

3.11.5.1—Lateral Earth Pressure

Lateral earth pressure shall be assumed to be linearly proportional to the depth of earth and taken as:

$$p = k\gamma_s z \quad (3.11.5.1-1)$$

where:

- p = lateral earth pressure (ksf)
- k = coefficient of lateral earth pressure taken as k_o , specified in Article 3.11.5.2, for walls that do not deflect or move; k_a , specified in Articles 3.11.5.3, 3.11.5.6, and 3.11.5.7, for walls that deflect or move sufficiently to reach minimum active conditions; or k_p , specified in Article 3.11.5.4, for walls that deflect or move sufficiently to reach a passive condition
- γ_s = unit weight of soil (kcf)
- z = depth below the surface of earth (ft)

The resultant lateral earth load due to the weight of the backfill shall be assumed to act at a height of $H/3$ above the base of the wall, where H is the total wall height, measured from the surface of the ground at the back of the wall to the bottom of the footing or the top of the leveling pad (for MSE walls).

The development of hydrostatic water pressure on walls should be eliminated through use of crushed rock, pipe drains, gravel drains, perforated drains or geosynthetic drains.

Pore water pressures behind the wall may be approximated by flow net procedures or various analytical methods.

C3.11.4

The Mononobe-Okabe method for determining equivalent static fluid pressures for seismic loads on gravity and semigravity retaining walls is presented in Appendix A11.

The Mononobe-Okabe analysis is based, in part, on the assumption that the backfill soils are unsaturated and thus, not susceptible to liquefaction.

Where soils are subject to both saturation and seismic or other cyclic/instantaneous loads, special consideration should be given to address the possibility of soil liquefaction.

C3.11.5.1

Although previous versions of these Specifications have required design of conventional gravity walls for a resultant earth pressure located $0.4H$ above the wall base, the current specifications require design for a resultant located $H/3$ above the base. This requirement is consistent with historical practice and with calibrated resistance factors in Section 11. The resultant lateral load due to the

earth pressure may act as high as $0.4 H$ above the base of the wall for a mass concrete gravity retaining wall, where H is the total wall height measured from the top of the backfill to the base of the footing, where the wall deflects laterally, i.e., translates, in response to lateral earth loading. For such structures, the backfill behind the wall must slide down along the back of the wall for the retained soil mass to achieve the active state of stress. Experimental results indicate that the backfill arches against the upper portion of the wall as the wall translates, causing an upward shift in the location at which the resultant of the lateral earth load is transferred to the wall (Terzaghi, 1934) (Clausen and Johansen et al., 1972) (Sherif et al., 1982). Such walls are not representative of typical gravity walls used in highway applications.

For most gravity walls which are representative of those used in highway construction, nongravity cantilever retaining walls or other flexible walls which tilt or deform laterally in response to lateral loading, e.g., MSE walls, as well as walls which cannot translate or tilt, e.g., integral abutment walls, significant arching of the backfill against the wall does not occur, and the resultant lateral load due to earth pressure acts at a height of $H/3$ above the base of the wall. Furthermore, where wall friction is not considered in the analysis, it is sufficiently conservative to use a resultant location of $H/3$, even if the wall can translate.

3.11.5.2—At-Rest Lateral Earth Pressure Coefficient, k_o

For normally consolidated soils, vertical wall, and level ground, the coefficient of at-rest lateral earth pressure may be taken as:

$$k_o = 1 - \sin \phi'_f \quad (3.11.5.2-1)$$

where:

ϕ'_f = effective internal friction angle of soil (degrees)
 k_o = coefficient of at-rest lateral earth pressure

For overconsolidated soils, the coefficient of at-rest lateral earth pressure may be assumed to vary as a function of the overconsolidation ratio or stress history, and may be taken as:

$$k_o = (1 - \sin \phi'_f) (OCR)^{\sin \phi'_f} \quad (3.11.5.2-2)$$

where:

OCR = overconsolidation ratio

Silt and lean clay shall not be used for backfill unless suitable design procedures are followed and construction control measures are incorporated in the construction documents to account for their presence. Consideration must be given for the development of pore water pressure

C3.11.5.2

For typical cantilevered walls over 5.0 ft high with structural grade backfill, calculations indicate that the horizontal movement of the top of the wall due to a combination of structural deformation of the stem and rotation of the foundation is sufficient to develop active conditions.

In many instances, the OCR may not be known with enough accuracy to calculate k_o using Eq. 3.11.5.2-2. Based on information on this issue provided by Holtz and Kovacs (1981), in general, for lightly overconsolidated sands ($OCR = 1$ to 2), k_o is in the range of 0.4 to 0.6. For highly overconsolidated sand, k_o can be on the order of 1.0.

The evaluation of the stress induced by cohesive soils is highly uncertain due to their sensitivity to shrink-swell, wet-dry and degree of saturation. Tension cracks can form, which considerably alter the assumptions for the estimation of stress. Extreme caution is advised in the

within the soil mass in accordance with Article 3.11.3. Appropriate drainage provisions shall be provided to prevent hydrostatic and seepage forces from developing behind the wall in accordance with the provisions of Section 11. In no case shall highly plastic clay be used for backfill.

For the design of rectangular reinforced concrete culverts, the lateral pressure coefficient, k_o , need not be taken greater than 0.5 for culverts embedded in granular soils.

3.11.5.3—Active Lateral Earth Pressure Coefficient, k_a

Values for the coefficient of active lateral earth pressure may be taken as:

$$k_a = \frac{\sin^2(\theta + \phi'_f)}{\Gamma [\sin^2 \theta \sin(\theta - \delta)]} \quad (3.11.5.3-1)$$

in which:

$$\Gamma = \left[1 + \sqrt{\frac{\sin(\phi'_f + \delta) \sin(\phi'_f - \beta)}{\sin(\theta - \delta) \sin(\theta + \beta)}} \right]^2 \quad (3.11.5.3-2)$$

where:

- δ = friction angle between fill and wall (degrees)
- β = angle of fill to the horizontal, as shown in Figure 3.11.5.3-1 (degrees)
- θ = angle of back face of wall to the horizontal, as shown in Figure 3.11.5.3-1 (degrees)
- ϕ'_f = effective angle of internal friction (degrees)

For conditions that deviate from those described in Figure 3.11.5.3-1, the active pressure may be calculated by using a trial procedure based on wedge theory using the Coulomb method (e.g., see Terzaghi et al., 1996).

determination of lateral earth pressures assuming the most unfavorable conditions. See Article C3.11.1 for additional guidance on estimating earth pressures in fine-grained soils. If possible, cohesive or other fine-grained soils should be avoided as backfill.

The lateral earth pressure on culverts is the same on both sides of the structure and usually produces small force effects relative to the effects due to vertical loads. The value of $k_o = 0.5$ has long been used and produces satisfactory designs.

C3.11.5.3

The values of k_a by Eq. 3.11.5.3-1 are based on the Coulomb earth pressure theories. The Coulomb theory is necessary for design of retaining walls for which the back face of the wall interferes with the development of the full sliding surfaces in the backfill soil assumed in Rankine theory (Figure C3.11.5.3-1 and Article C3.11.5.3). Either Coulomb or Rankine wedge theory may be used for long heeled cantilever walls shown in Figure C3.11.5.3-1a. In general, Coulomb wedge theory applies for gravity, semigravity, prefabricated modular, and MSE walls, and concrete cantilever walls with short heels.

Table C3.11.5.3-1 provides typical values for the nominal interface friction angle δ between the back of the wall and backfill for a range of materials and soils. These values are presumptive in nature and are therefore likely to be conservative. Alternatively, long-term practice has been to use $\delta = 0.67\phi'_f$ at the interface between the back of the wall and the retained soil to calculate k_a for soil against concrete as well as soil against steel. For soil against steel, $\delta = 0.33\phi'_f$ has typically been used. This is usually conservative for noncohesive soils. For sliding resistance calculations, Article 10.6.3.4 indicates that $\tan \delta = 0.80 \tan \phi'_f$ should be used for footing sliding resistance, if the footing is precast concrete, and $\tan \delta = \tan \phi_f$ if the footing concrete is cast directly on the foundation soil. Additional information on friction values of various materials against soil is provided in Potyondy (1961), which is a key source for these friction values. In the absence of specific test data such as measured ϕ_f from laboratory testing, ϕ_f determined through correlation to in-situ measured SPT, or cone resistance values, the values in Table C3.11.5.3-1 or $\delta = 0.67\phi'_f$ may be used in computations that include effects of wall friction. To estimate sliding resistance along the base of a wall or footing foundation, Table C3.11.5.3-1, $\tan \delta = 0.80 \tan \phi'_f$ if the footing is precast concrete, or $\tan \delta = \tan \phi_f$ if the footing concrete is cast directly on the foundation soil may be used. Based on the work by Potyondy (1961), all these values are likely to be conservative.

If the wall friction acting on the back of the wall is for soil against soil, such as occurs for semigravity and MSE walls, theoretically δ could be as high as the soil friction angle. However, even for semigravity cantilever walls in which most of the wall friction surface assumed is soil on

soil, the wall friction is usually limited to $0.67\phi'_f$ of the reinforced or retained soil, whichever is lower, for design. For sliding resistance, the reduction in friction angle at the interface with the wall base or structure footing is typically applied to $\tan \phi'_f$ rather than directly to ϕ'_f (e.g., see Articles 10.6.3.4 and C10.6.3.4 with regard to sliding frictional resistance). However, for wall friction used to determine the k_a value, δ is used directly in the rather complex k_a equation, and it is more practical to simply reduce the value of ϕ'_f .

For the cantilever wall in Figure C3.11.5.3-1b, the earth pressure is applied to a plane extending vertically up from the heel of the wall base, and the weight of soil to the left of the vertical plane is considered as part of the wall weight.

The differences between the Coulomb theory currently specified, and the Rankine theory specified in the past is illustrated in Figure C3.11.5.3-1. The Rankine theory is the basis of the equivalent fluid method of Article 3.11.5.5.

Silt and lean clay should not be used for backfill where free-draining granular materials are available. When using poorly draining silts or cohesive soils, extreme caution is advised in the determination of lateral earth pressures assuming the most unfavorable conditions. Consideration must be given for the development of pore water pressure within the soil mass in accordance with Article 3.11.3. Appropriate drainage provisions should be provided to prevent hydrostatic and seepage forces from developing behind the wall in accordance with the provisions in Section 11. In no case should highly plastic clay be used for backfill.

Figure 3.11.5.3-1—Notation for Coulomb Active Earth Pressure

Figure C3.11.5.3-1—Application of (a) Rankine and (b) Coulomb Earth Pressure Theories in Retaining Wall Design

Table C3.11.5.3-1—Friction Angle for Dissimilar Materials (U.S. Department of the Navy, 1982)

Interface Materials	Friction Angle, δ (degrees)	Coefficient of Friction, $\tan \delta$ (dim.)
Mass concrete on the following foundation materials:		
• Clean sound rock	35	0.70
• Clean gravel, gravel-sand mixtures, coarse sand	29 to 31	0.55 to 0.60
• Clean fine to medium sand, silty medium to coarse sand, silty or clayey gravel	24 to 29	0.45 to 0.55
• Clean fine sand, silty or clayey fine to medium sand	19 to 24	0.34 to 0.45
• Fine sandy silt, nonplastic silt	17 to 19	0.31 to 0.34
• Very stiff and hard residual or preconsolidated clay	22 to 26	0.40 to 0.49
• Medium stiff and stiff clay and silty clay	17 to 19	0.31 to 0.34
Masonry on foundation materials has same friction factors.		
Steel sheet piles against the following soils:		
• Clean gravel, gravel-sand mixtures, well-graded rock fill with spalls	22	0.40
• Clean sand, silty sand-gravel mixture, single-size hard rock fill	17	0.31
• Silty sand, gravel or sand mixed with silt or clay	14	0.25
• Fine sandy silt, nonplastic silt	11	0.19
Formed or precast concrete or concrete sheet piling against the following soils:		
• Clean gravel, gravel-sand mixture, well-graded rock fill with spalls	22 to 26	0.40 to 0.49
• Clean sand, silty sand-gravel mixture, single-size hard rock fill	17 to 22	0.31 to 0.40
• Silty sand, gravel or sand mixed with silt or clay	17	0.31
• Fine sandy silt, nonplastic silt	14	0.25
Various structural materials:		
• Masonry on masonry, igneous and metamorphic rocks:		
○ dressed soft rock on dressed soft rock	35	0.70
○ dressed hard rock on dressed soft rock	33	0.65
○ dressed hard rock on dressed hard rock	29	0.55
• Masonry on wood in direction of cross grain	26	0.49
• Steel on steel at sheet pile interlocks	17	0.31

3.11.5.4—Passive Lateral Earth Pressure Coefficient, k_p

For noncohesive soils, values of the coefficient of passive lateral earth pressure may be taken from Figure 3.11.5.4-1 for the case of a sloping or vertical wall with a horizontal backfill or from Figure 3.11.5.4-2 for the case of a vertical wall and sloping backfill. For conditions that deviate from those described in Figures 3.11.5.4-1 and 3.11.5.4-2, the passive pressure may be calculated by using a trial procedure based on wedge theory, e.g., see Terzaghi et al. (1996). When wedge theory is used, the limiting value of the wall friction angle should not be taken larger than one-half the angle of internal friction, ϕ_r .

For cohesive soils, passive pressures may be estimated by:

C3.11.5.4

The movement required to mobilize passive pressure is approximately 10.0 times as large as the movement needed to induce earth pressure to the active values. The movement required to mobilize full passive pressure in loose sand is approximately five percent of the height of the face on which the passive pressure acts. For dense sand, the movement required to mobilize full passive pressure is smaller than five percent of the height of the face on which the passive pressure acts, and five percent represents a conservative estimate of the movement required to mobilize the full passive pressure. For poorly compacted cohesive soils, the movement required to mobilize full passive pressure is larger than five percent of the height of the face on which the pressure acts.

$$p_p = k_p \gamma_s z + 2c \sqrt{k_p} \quad (3.11.5.4-1)$$

Wedge solutions are inaccurate and unconservative for larger values of wall friction angle.

where:

- p_p = passive lateral earth pressure (ksf)
 γ_s = unit weight of soil (kcf)
 z = depth below surface of soil (ft)
 c = soil cohesion (ksf)
 k_p = coefficient of passive lateral earth pressure specified in Figures 3.11.5.4-1 and 3.11.5.4-2, as appropriate

$$k_p = R k'_p \quad (3.11.5.4-2)$$

where:

- k_p = coefficient of passive lateral earth pressure
 R = reduction factor for coefficient of passive lateral earth pressure for various ratios of $-\delta/\phi_f$
 k'_p = intermediate coefficient of passive lateral earth pressure determined from Figures 3.11.5.4-1 and 3.11.5.4-2

Figure 3.11.5.4-1—Computational Procedures for Passive Earth Pressures for Vertical and Sloping Walls with Horizontal Backfill (U.S. Department of the Navy, 1982)

Figure 3.11.5.4-2—Computational Procedures for Passive Earth Pressures for Vertical Wall with Sloping Backfill (U.S. Department of the Navy, 1982)

3.11.5.5—Equivalent-Fluid Method of Estimating Rankine Lateral Earth Pressures

The equivalent-fluid method may be used where Rankine earth pressure theory is applicable.

The equivalent-fluid method shall only be used where the backfill is free-draining. If this criterion cannot be satisfied, the provisions of Articles 3.11.3, 3.11.5.1, and 3.11.5.3 shall be used to determine horizontal earth pressure.

C3.11.5.5

Applicability of Rankine theory is discussed in Article C3.11.5.3.

Values of the unit weights of equivalent fluids are given for walls that can tolerate very little or no movement as well as for walls that can move as much as 1.0 in. in 20.0 ft. The concepts of equivalent fluid unit weights have taken into account the effect of soil creep on walls.

Where the equivalent-fluid method is used, the basic earth pressure, p (ksf), may be taken as:

$$p = \gamma_{eq} z \quad (3.11.5.5-1)$$

where:

- γ_{eq} = equivalent fluid unit weight of soil, not less than 0.030 (kef)
 z = depth below surface of soil (ft)

The resultant lateral earth load due to the weight of the backfill shall be assumed to act at a height of $H/3$ above the base of the wall, where H is the total wall height, measured from the surface of the ground to the bottom of the footing.

Typical values for equivalent fluid unit weights for design of a wall of height not exceeding 20.0 ft may be taken from Table 3.11.5.5-1, where:

- Δ = movement of top of wall required to reach minimum active or maximum passive pressure by tilting or lateral translation (ft)
 H = height of wall (ft)
 β = angle of fill to the horizontal (degrees)

The magnitude of the vertical component of the earth pressure resultant for the case of sloping backfill surface may be determined as:

$$P_v = P_h \tan \beta \quad (3.11.5.5-2)$$

where:

$$P_h = 0.5 \gamma_{eq} H^2 \quad (3.11.5.5-3)$$

If the backfill qualifies as free-draining (i.e., granular material with less than 5 percent passing a No. 200 sieve), water is prevented from creating hydrostatic pressure.

For discussion on the location of the resultant of the lateral earth force, see Article C3.11.5.1.

The values of equivalent fluid unit weight presented in Table 3.11.5.5-1 for $\Delta/H = 1/240$ represent the horizontal component of active earth pressure based on Rankine earth pressure theory. This horizontal earth pressure is applicable for cantilever retaining walls for which the wall stem does not interfere with the sliding surface defining the Rankine failure wedge within the wall backfill (Figure C3.11.5.3-1). The horizontal pressure is applied to a vertical plane extending up from the heel of the wall base, and the weight of soil to the left of the vertical plane is included as part of the wall weight.

For the case of a sloping backfill surface in Table 3.11.5.5-1, a vertical component of earth pressure also acts on the vertical plane extending up from the heel of the wall.

Table 3.11.5.5-1—Typical Values for Equivalent Fluid Unit Weights of Soils

Type of Soil	Level Backfill		Backfill with $\beta = 25$ degrees	
	At-Rest γ_{eq} (kef)	Active $\Delta/H = 1/240$ γ_{eq} (kef)	At-Rest γ_{eq} (kef)	Active $\Delta/H = 1/240$ γ_{eq} (kef)
Loose sand or gravel	0.055	0.040	0.065	0.050
Medium dense sand or gravel	0.050	0.035	0.060	0.045
Dense sand or gravel	0.045	0.030	0.055	0.040

3.11.5.6—Lateral Earth Pressures for Nongravity Cantilevered Walls

For permanent walls, the simplified lateral earth pressure distributions shown in Figures 3.11.5.6-1 through 3.11.5.6-3 may be used. If walls will support or are supported by cohesive soils for temporary applications, walls may be designed based on total stress methods of analysis and undrained shear strength parameters. For this latter case, the simplified earth pressure distributions shown in Figures 3.11.5.6-4 through 3.11.5.6-7 may be used with the following restrictions:

- The ratio of total overburden pressure to undrained shear strength, N_s (see Article 3.11.5.7.2), should be <3 at the wall base.
- The active earth pressure shall not be less than 0.25 times the effective overburden pressure at any depth, or 0.035 ksf/ft of wall height, whichever is greater.

For temporary walls with discrete vertical elements embedded in granular soil or rock, Figures 3.11.5.6-1 and 3.11.5.6-2 may be used to determine passive resistance and Figures 3.11.5.6-4 and 3.11.5.6-5 may be used to determine the active earth pressure due to the retained soil.

Where discrete vertical wall elements are used for support, the width, b , of each vertical element shall be assumed to equal the width of the flange or diameter of the element for driven sections and the diameter of the concrete-filled hole for sections encased in concrete.

The magnitude of the sloping surcharge above the wall for the determination of P_{a2} in Figure 3.11.5.6-4 should be based on the wedge of soil above the wall within the active wedge.

In Figure 3.11.5.6-5, a portion of negative loading at top of wall due to cohesion is ignored and hydrostatic pressure in a tension crack should be considered, but is not shown on the figure.

C3.11.5.6

Nongravity cantilevered walls temporarily supporting or supported by cohesive soils are subject to excessive lateral deformation if the undrained soil shear strength is low compared to the shear stresses. Therefore, use of these walls should be limited to soils of adequate strength as represented by the stability number, N_s (see Article 3.11.5.7.2).

Base movements in the soil in front of a wall become significant for values of N_s of about 3 to 4, and a base failure can occur when N_s exceeds about 5 to 6 (Terzaghi and Peck, 1967).

In Figures 3.11.5.6-1, 3.11.5.6-2, 3.11.5.6-4, and 3.11.5.6-5, the width, b , of discrete vertical wall elements effective in mobilizing the passive resistance of the soil is based on the Broms Method of analysis for single vertical piles embedded in cohesive or cohesionless soil and assumes a vertical element. The effective width for passive resistance of three times the element width, $3b$, is due to the arching action in soil and side shear on resisting rock wedges. The maximum width of $3b$ can be used when material in which the vertical element is embedded does not contain discontinuities that would affect the failure geometry. This width should be reduced if planes or zones of weakness would prevent mobilization of resistance through this entire width, or if the passive resistance zones of adjacent elements overlap. If the element is embedded in soft clay having a stability number less than three, soil arching will not occur and the actual width shall be used as the effective width for passive resistance. Where a vertical element is embedded in rock, i.e., Figure 3.11.5.6-2, the passive resistance of the rock is assumed to develop through the shear failure of a rock wedge equal in width to the vertical element, b , and defined by a plane extending upward from the base of the element at an angle of 45 degrees. For the active zone behind the wall below the mudline or groundline in front of the wall, the active pressure is assumed to act over one vertical element width, b , in all cases.

The Broms (1964a, 1964b) approach of accounting for soil arching assumed the use of Rankine theory passive pressure coefficients. Therefore, Rankine theory passive earth pressure coefficients should be used when using soil arching to increase the effective width of the vertical elements. When in the unusual case the ground slope β' is negative (i.e., the ground slopes up away from the wall

face), due to the trigonometric functions used in Eq. 3.11.5.6-1, the passive earth pressure coefficient decreases again as the ground slope becomes more negative. Hence, it is recommended that the ground surface in front of the wall be assumed to be flat when β' is negative.

The design grade is generally taken below finished grade to account for excavation during or after wall construction or other disturbance to the supporting soil during the service life of the wall.

In Figures 3.11.5.6-3, 3.11.5.6-6, and 3.11.5.6-7, the depth of embedment for the continuous vertical wall elements is shown as $D \approx 1.2 D_o$. In these cases, a simplified method of design (see Article C11.8.4.1) is used which simplifies some computational work, but results in a small error in the calculated embedment depth, where D_o is slightly smaller than D calculated by a more rigorous calculation method. Typical practice has been to increase this depth by approximately 20 percent to accommodate the small error caused by this simplification.

b = ACTUAL WIDTH OF EMBEDDED DISCRETE VERTICAL WALL ELEMENT BELOW DESIGN GRADE IN PLANE OF WALL (FT.).

Figure 3.11.5.6-1—Unfactored Simplified Earth Pressure Distributions for Permanent Nongravity Cantilevered Walls with Discrete Vertical Wall Elements Embedded in Granular Soil

b = ACTUAL WIDTH OF EMBEDDED DISCRETE VERTICAL WALL ELEMENT BELOW DESIGN GRADE IN PLANE OF WALL (FT.).

Figure 3.11.5.6-2—Unfactored Simplified Earth Pressure Distributions for Permanent Nongravity Cantilevered Walls with Discrete Vertical Wall Elements Embedded in Rock

b = ACTUAL WIDTH OF EMBEDDED DISCRETE VERTICAL WALL ELEMENT BELOW DESIGN GRADE IN PLANE OF WALL (FT.).

Figure 3.11.5.6-4—Unfactored Simplified Earth Pressure Distributions for Temporary Nongravity Cantilevered Walls with Discrete Vertical Wall Elements Embedded in Cohesive Soil and Retaining Granular Soil

b = ACTUAL WIDTH OF EMBEDDED DISCRETE VERTICAL WALL ELEMENT BELOW DESIGN GRADE IN PLANE OF WALL (FT.).

Figure 3.11.5.6-5—Unfactored Simplified Earth Pressure Distributions for Temporary Nongravity Cantilevered Walls with Discrete Vertical Wall Elements Embedded in Cohesive Soil and Retaining Cohesive Soil

Note: For walls embedded in granular soil, refer to Figure 3.11.5.6.3-3 and use Figure 3.11.5.6-7 for retained cohesive soil, when appropriate.

Figure 3.11.5.6-6—Unfactored Simplified Earth Pressure Distributions for Temporary Nongravity Cantilevered Walls with Continuous Vertical Wall Elements Embedded in Cohesive Soil and Retaining Granular Soil Modified after Teng (1962)

Figure 3.11.5.6-7—Unfactored Simplified Earth Pressure Distributions for Temporary Nongravity Cantilevered Walls with Continuous Vertical Wall Elements Embedded in Cohesive Soil and Retaining Cohesive Soil Modified after Teng (1962)

If the effective width of the discrete vertical elements used to calculate passive resistance is greater than the actual width of the vertical element b due to soil arching, Rankine theory shall be used to calculate the passive lateral earth pressure coefficient if the ground in front of the wall is level or sloping downhill away from the wall. For sloping ground in granular soils, the following Rankine theory based equation shall be used to calculate K_p in this case:

$$K_p = \frac{\cos \beta' + \sqrt{(\cos^2 \beta' - \cos^2 \phi_p)}}{\cos \beta' - \sqrt{(\cos^2 \beta' - \cos^2 \phi_p)}} \quad (3.11.5.6-1)$$

where:

- β' = slope angle for finished grade, defined as positive, as shown in Figure 3.11.5.6-1 (degrees)
 ϕ_p = soil friction angle for soil within passive resistance zone (degrees)

If, in the unusual case, β' is negative (i.e., sloping up away from the wall in the passive zone), the ground in front of the wall should be assumed to be flat.

3.11.5.7—*AEP* for Anchored Walls

For anchored walls constructed from the top down, the earth pressure may be estimated in accordance with Articles 3.11.5.7.1 or 3.11.5.7.2.

In developing the design pressure for an anchored wall, consideration shall be given to wall displacements that may affect adjacent structures and/or underground utilities.

C3.11.5.7

In the development of lateral earth pressures, the method and sequence of construction, the rigidity of the wall/anchor system, the physical characteristics and stability of the ground mass to be supported, allowable wall deflections, anchor spacing and prestress and the potential for anchor yield should be considered.

Several suitable *AEP* distribution diagrams are available and in common use for the design of anchored walls, e.g., Sabatini et al. (1999), Cheney (1988), and U.S. Department of the Navy (1982). Some of the *AEP* diagrams, such as those described in Articles 3.11.5.7.1 and 3.11.5.7.2, are based on the results of measurements on anchored walls, Sabatini et al. (1999). Others are based on the results of measurements on strutted excavations (Terzaghi and Peck, 1967), the results of analytical and scale model studies, (Clough and Tsui, 1974) (Hanna and Matallana, 1970); and observations of anchored wall installations (Nicholson et al., 1981) (Schnabel, 1982). While the results of these efforts provide somewhat different and occasionally conflicting results, they all tend to confirm the presence of higher lateral pressures near the top of the wall than would be predicted by classical earth pressure theories, due to the constraint provided by the upper level of anchors, and a generally uniform pressure distribution with depth.

3.11.5.7.1—*Cohesionless Soils*

The earth pressure on temporary or permanent anchored walls constructed in cohesionless soils may be determined using Figure 3.11.5.7.1-1, for which the maximum ordinate, p_a , of the pressure diagram is computed as follows:

For walls with one anchor level:

$$p_a = k_a \gamma'_s H \quad (3.11.5.7.1-1)$$

For walls with multiple anchor levels:

$$p_a = \frac{k_a \gamma'_s H^2}{1.5H - 0.5H_1 - 0.5H_{n+1}} \quad (3.11.5.7.1-2)$$

where:

- p_a = maximum ordinate of pressure diagram (ksf)
- k_a = active earth pressure coefficient
- = $\tan^2 (45 \text{ degrees} - \phi_f/2)$ (dim.) for $\beta = 0$
- use Eq. 3.11.5.3-1 for $\beta \neq 0$
- γ'_s = effective unit weight of soil (kcf)
- H = total excavation depth (ft)
- H_l = distance from ground surface to uppermost ground anchor (ft)
- H_{n+l} = distance from base of excavation to lowermost ground anchor (ft)
- T_{hi} = horizontal load in ground anchor, i (kip/ft)
- R = reaction force to be resisted by subgrade (i.e., below base of excavation) (kip/ft)

Figure 3.11.5.7.1-1—AEP Distributions for Anchored Walls Constructed from the Top Down in Cohesionless Soils

3.11.5.7.2—Cohesive Soils

The *AEP* distribution for cohesive soils is related to the stability number, N_s , which is defined as:

$$N_s = \frac{\gamma_s H}{S_u} \quad (3.11.5.7.2-1)$$

where:

- γ_s = total unit weight of soil (kcf)
 H = total excavation depth (ft)
 S_u = average undrained shear strength of soil (ksf)

3.11.5.7.2a—Stiff to Hard

For temporary anchored walls in stiff to hard cohesive soils ($N_s \leq 4$), the earth pressure may be determined using Figure 3.11.5.7.1-1, with the maximum ordinate, p_a , of the pressure diagram computed as:

$$p_a = 0.2\gamma_s H \text{ to } 0.4\gamma_s H \quad (3.11.5.7.2a-1)$$

where:

- p_a = maximum ordinate of pressure diagram (ksf)
 γ_s = total unit weight of soil (kcf)
 H = total excavation depth (ft)

For permanent anchored walls in stiff to hard cohesive soils, the *AEP* distributions described in Article 3.11.5.7.1 may be used with k_a based on the drained friction angle of the cohesive soil. For permanent walls, the distribution, permanent or temporary, resulting in the maximum total force shall be used for design.

3.11.5.7.2b—Soft to Medium Stiff

The earth pressure on temporary or permanent walls in soft to medium stiff cohesive soils ($N_s \geq 6$) may be determined using Figure 3.11.5.7.2b-1, for which the maximum ordinate, p_a , of the pressure diagram is computed as:

$$p_a = k_a \gamma_s H \quad (3.11.5.7.2b-1)$$

where:

- p_a = maximum ordinate of pressure diagram (ksf)
 k_a = active earth pressure coefficient from Eq. 3.11.5.7.2b-2
 γ_s = total unit weight of soil (kcf)
 H = total excavation depth (ft)

The active earth pressure coefficient, k_a , may be determined by:

$$k_a = 1 - \frac{4S_u}{\gamma_s H} + 2\sqrt{2} \frac{d}{H} \left(1 - \frac{5.14S_{ub}}{\gamma_s H} \right) \geq 0.22 \quad (3.11.5.7.2b-2)$$

where:

- S_u = undrained strength of retained soil (ksf)
 S_{ub} = undrained strength of soil below excavation base (ksf)
 γ_s = total unit weight of retained soil (kcf)
 H = total excavation depth (ft)
 d = depth of potential base failure surface below base of excavation (ft)

C3.11.5.7.2a

The determination of earth pressures in cohesive soils described in this Article and Article 3.11.5.7.2b are based on the results of measurements on anchored walls, Sabatini et al. (1999). In the absence of specific experience in a particular deposit, $p_a = 0.3\gamma_s H$ should be used for the maximum pressure ordinate when ground anchors are locked off at 75 percent of the unfactored design load or less. Where anchors are to be locked off at 100 percent of the unfactored design load or greater, a maximum pressure ordinate of $p_a = 0.4\gamma_s H$ should be used.

For temporary walls, the *AEP* distribution in Figure 3.11.5.7.1-1 should only be used for excavations of controlled short duration, where the soil is not fissured and where there is no available free water.

Temporary loading may control design of permanent walls and should be evaluated in addition to permanent loading.

C3.11.5.7.2b

For soils with $4 < N_s < 6$, use the larger p_a from Eq. 3.11.5.7.2a-1 and Eq. 3.11.5.7.2b-1.

The value of d is taken as the thickness of soft to medium stiff cohesive soil below the excavation base up to a maximum value of $B_e/\sqrt{2}$, where B_e is the excavation width.

Figure 3.11.5.7.2b-1—AEP Distribution for Anchored Walls Constructed from the Top Down in Soft to Medium Stiff Cohesive Soils

3.11.5.8—Lateral Earth Pressures for Mechanically Stabilized Earth Walls

3.11.5.8.1—General

The resultant force per unit width behind an MSE wall, shown in Figures 3.11.5.8.1-1, C3.11.5.8.1-1, and 3.11.5.8.1-2 as acting at a height of $h/3$ above the base of the wall, shall be taken as:

$$P_a = 0.5k_a\gamma_s h^2 \quad (3.11.5.8.1-1)$$

where:

- P_a = force resultant per unit width (kip/ft)
- γ_s = total unit weight of backfill (kcf)
- h = height of horizontal earth pressure diagram taken as shown in Figures 3.11.5.8.1-1, C3.11.5.8.1-1, and 3.11.5.8.1-2 (ft)
- k_a = active earth pressure coefficient specified in Article 3.11.5.3, with the angle of backfill slope taken as β , and the friction angle between soil zones taken as δ as specified in Figures 3.11.5.8.1-1, C3.11.5.8.1-1, and 3.11.5.8.1-2. δ should be no greater than $0.67\phi'_f$ of the reinforced or retained soil zone, whichever is lower.

For “broken back” soil surcharge conditions, a generalized limit equilibrium (GLE) analysis, as presented in Article A11.3.3, or a Coulomb trial wedge analysis should be used.

C3.11.5.8.1

MSE wall Figures 3.11.5.8.1-1 and 3.11.5.8.1-2 are based on a Coulomb external load model consistent with the analysis of all other gravity walls. For MSE walls, the back of the reinforced soil zone is assumed to define the plane upon which wall friction acts. See Article C3.11.5.3 for guidance and background on the determination of wall friction angles for calculating earth pressure coefficients. Rankine theory may be used to calculate k_a for external stability evaluation using $\delta = \beta$ of the finished slope. Rankine theory will typically produce more conservative results. However, the Rankine $\delta = \beta$ should only be used in combination with Rankine theory, and δ = the angle of friction between the back of the wall and the soil behind the wall should only be used with Coulomb theory.

For “broken back” soil surcharge conditions, the Coulomb load model also permits a direct solution using a trial wedge analysis. A simplified alternative for broken back surcharge conditions is also provided in Figure C3.11.5.8.1-1 and may be used, since long-term practice has been to use this simplified approach. This simplified approach may be used with Rankine theory as well, but with δ replaced with β' .

Figure 3.11.5.8.1-1—Earth Pressure Distribution for MSE Wall with Level Backfill Surface

Figure 3.11.5.8.1-2—Earth Pressure Distribution for MSE Wall with Sloping Backfill Surface

3.11.5.8.2—Internal Stability

The load factor γ_p to be applied to the maximum load carried by the reinforcement T_{max} for reinforcement strength, connection strength, and pullout calculations (see Article 11.10.6.2) shall be γ_{p-EV} , for vertical earth pressure.

For MSE walls, η_i shall be taken as 1.

Figure C3.11.5.8.1-1—Earth Pressure Distribution for MSE Wall with Broken Back Earth Surcharge

C3.11.5.8.2

Loads carried by the soil reinforcement in mechanically stabilized earth walls are the result of vertical and lateral earth pressures which exist within the reinforced soil mass, reinforcement extensibility, facing stiffness, wall toe restraint, and the stiffness and strength of the soil backfill within the reinforced soil mass. The calculation method for T_{max} is empirically derived, based on reinforcement strain measurements, converted to load based on the reinforcement stiffness, from full scale walls during or at end of wall construction. The primary source of these reinforcement loads is the gravity forces acting on the reinforced soil mass plus any soil surcharge present. Hence, the load factor γ_{p-EV} as specified in Table 3.4.1-2 is used for the soil loads acting on the reinforcements. If there are concentrated surcharge loads acting on the reinforced soil mass (e.g., structure footings – see Article 3.11.6.2), such surcharge loads should be added to the gravity loads acting on the reinforcement by superposition, and the appropriate load factor applied to the concentrated surcharge load from Table 3.4.1-2.

For MSE wall internal stability using the Stiffness Method, when addressing the soil failure, the load factor is designated as γ_{p-EVsf} . This load factor was developed for the Service Limit (see Article 11.10.4.3).

3.11.5.9—Lateral Earth Pressures for Prefabricated Modular Walls

C3.11.5.9

The magnitude and location of resultant loads and resisting forces for prefabricated modular walls may be determined using the earth pressure distributions presented in Figures 3.11.5.9-1 and 3.11.5.9-2. Where the back of the prefabricated modules forms an irregular, stepped surface, the earth pressure shall be computed on a plane surface drawn from the upper back corner of the top module to the lower back heel of the bottom module using Coulomb earth pressure theory.

Prefabricated modular walls are gravity walls constructed of prefabricated concrete elements that are in-filled with soil. They differ from modular block MSE structures in that they contain no soil reinforcing elements.

Figure 3.11.5.9-1—Earth Pressure Distributions for Prefabricated Modular Walls with Continuous Pressure Surfaces

Figure 3.11.5.9-2—Earth Pressure Distributions for Prefabricated Modular Walls with Irregular Pressure Surfaces

The value of k_a used to compute lateral thrust resulting from retained backfill and other loads behind the wall shall be computed based on the friction angle of the backfill behind the modules. In the absence of specific data, if granular backfill is used behind the prefabricated modules within a zone of at least 1V:1H from the heel of the wall, a value of 34 degrees may be used for ϕ_f . Otherwise, without specific data, a maximum friction angle of 30 degrees shall be used.

The wall friction angle, δ , is a function of the direction and magnitude of possible movements, and the properties of the backfill. When the structure settles more than the backfill, the wall friction angle is negative.

As a maximum, the wall friction angles, given in Table C3.11.5.9-1, should be used to compute k_a , unless more exact coefficients are demonstrated:

Table C3.11.5.9-1—Maximum Wall Friction Angles, δ

Case	Wall Friction Angle (δ)
Modules settle more than backfill	0
Continuous pressure surface of precast concrete (uniform width modules)	$0.50 \phi_f$
Average pressure surface (stepped modules)	$0.75 \phi_f$

3.11.5.10—Lateral Earth Pressures for Sound Barriers Supported on Discrete and Continuous Vertical Embedded Elements

For sound barriers supported on discrete vertical wall elements embedded in granular soil, rock, or cohesive soil, the simplified lateral earth pressure distributions shown

C3.11.5.10

Earth pressure on foundations of sound barriers is similar to that on nongravity retaining walls discussed in Article 3.11.5.6 except that the soil elevation on both sides

in Figures 3.11.5.10-1, 3.11.5.10-2, and 3.11.5.10-3, respectively, may be used. For sound barriers supported on continuous vertical elements embedded in granular soil or cohesive soil, the simplified earth pressure distributions shown in Figures 3.11.5.10-4 and 3.11.5.10-5, respectively, may be used. For sound barriers supported on retaining walls, the applicable provisions of Section 11 shall apply.

Where discrete vertical elements are used for support, the width, b , of each vertical element shall be assumed to equal the width of the flange or diameter of the element for driven sections and the diameter of the concrete-filled hole for sections encased in concrete.

The reversal in the direction of applied lateral forces on sound barriers shall be considered in the design.

of the wall is often the same or, if there is a difference, does not reach the top of the wall on one side. The provisions of this Article are applicable to the foundations of any wall that is not primarily intended to retain earth, i.e. there is no or little difference in the elevation of fill on either side of the wall.

In Figures 3.11.5.10-1 and 3.11.5.10-3, the width, b , of discrete vertical elements effective in mobilizing the passive resistance of the soil is based on a method of analysis by Broms (1964a, 1964b) for single vertical piles embedded in cohesive or granular soil. Additional information on the background of the earth pressure on discrete vertical elements is presented in Article C3.11.5.6.

The main applied lateral forces on sound barriers are wind and seismic forces; both of them are reversible. When the ground surface in front of or behind the sound barrier, or both, is not flat or the ground surface is not at the same elevation on both sides of the sound barrier, the design should be checked assuming that the lateral force is applied in either direction. The effect of the direction of ground surface slope, i.e. toward the barrier or away from the barrier, should be considered in earth pressure calculations for both directions of lateral loads. The earth pressure diagrams shown in Figures 3.11.5.10-1 through 3.11.5.10-5 correspond to the lateral load direction shown in these figures.

Figure 3.11.5.10-1—Unfactored Simplified Earth Pressure Distributions for Discrete Vertical Wall Elements Embedded in Granular Soil

Figure 3.11.5.10-3—Unfactored Simplified Earth Pressure Distributions for Discrete Vertical Wall Elements Embedded in Cohesive Soil

Figure 3.11.5.10-4—Unfactored Simplified Earth Pressure Distributions for Continuous Vertical Elements Embedded in Granular Soil Modified after Teng (1962)

Figure 3.11.5.10-5—Unfactored Simplified Earth Pressure Distributions for Continuous Vertical Wall Elements Embedded in Cohesive Soil Modified after Teng (1962)

3.11.6—Surcharge Loads: *ES* and *LS*

The factored soil stress increase behind or within the wall caused by concentrated surcharge loads or stresses shall be the greater of (1) the unfactored surcharge loads or stresses multiplied by the specified load factor, *ES*, or (2) the factored loads for the structure as applied to the

C3.11.6

Concentrated surcharge loads induced by foundations are typically the result of dead load, live load, wind load, and possibly other loads that are associated with load factors other than *ES*. However, the controlling uncertainty in load prediction for surcharges is the

structural element causing the surcharge load, setting ES to 1.0. The load applied to the wall due to the structural element above the wall shall not be double factored.

3.11.6.1—Uniform Surcharge Loads (ES)

Where a uniform surcharge is present, a constant horizontal earth pressure shall be added to the basic earth pressure. This constant earth pressure may be taken as:

$$\Delta_p = k_s q_s \quad (3.11.6.1-1)$$

where:

- Δ_p = constant horizontal earth pressure due to uniform surcharge (ksf)
- k_s = coefficient of earth pressure due to surcharge
- q_s = uniform surcharge applied to the upper surface of the active earth wedge (ksf)

For active earth pressure conditions, k_s shall be taken as k_a , and for at-rest conditions, k_s shall be taken as k_o . Otherwise, intermediate values appropriate for the type of backfill and amount of wall movement may be used.

3.11.6.2—Point, Line, and Strip Loads (ES): Walls Restrained from Movement

The horizontal pressure, Δ_{ph} in ksf, on a wall resulting from a uniformly loaded strip parallel to the wall may be taken as:

$$\Delta_{ph} = \frac{2p}{\pi} [\delta - \sin \delta \cos (\delta + 2\alpha)] \quad (3.11.6.2-1)$$

where:

- p = uniform load intensity on strip parallel to wall (ksf)
- α = angle specified in Figure 3.11.6.2-1 (rad)
- δ = angle specified in Figure 3.11.6.2-1 (rad)

transmission of the surcharge load through the soil to the wall or other structure below the surcharge. Hence, ES should be applied to the unfactored concentrated surcharge loads, unless the combined effect of the factored loads applicable to the foundation unit transmitting load to the top of the wall is more conservative. In this latter case, ES should be set equal to 1.0 and the factored footing loads used as the concentrated surcharge load in the wall design.

C3.11.6.1

When the uniform surcharge is produced by an earth loading on the upper surface, the load factor for both vertical and horizontal components shall be taken as specified in Table 3.4.1-2 for earth surcharge.

Wall movement needed to mobilize extreme active and passive pressures for various types of backfill can be found in Table C3.11.1-1.

C3.11.6.2

Eqs. 3.11.6.2-1, 3.11.6.2-2, 3.11.6.2-3, and 3.11.6.2-4 are based on the assumption that the wall does not move, i.e., walls which have a high degree of structural rigidity or restrained at the top combined with an inability to slide in response to applied loads. For flexible walls, this assumption can be very conservative. Additional guidance regarding the ability of walls to move is provided in Article C3.11.1.

Figure 3.11.6.2-1—Horizontal Pressure on Wall Caused by a Uniformly Loaded Strip

The horizontal pressure, Δ_{ph} in ksf, on a wall resulting from a point load may be taken as:

$$\Delta_{ph} = \frac{P}{\pi R^2} \left[\frac{3ZX^2}{R^3} - \frac{R(1-2\nu)}{R+Z} \right] \quad (3.11.6.2-2)$$

where:

- P = point load (kip)
- R = radial distance from point of load application to a point on the wall as specified in Figure 3.11.6.2-2 where $R = (X^2 + Y^2 + Z^2)^{0.5}$ (ft)
- X = horizontal distance from back of wall to point of load application (ft)
- Y = horizontal distance from point on the wall under consideration to a plane, which is perpendicular to the wall and passes through the point of load application measured along the wall (ft)
- Z = vertical distance from point of load application to the elevation of a point on the wall under consideration (ft)
- ν = Poisson's ratio (dim.)

The point on the wall does not have to lie in a plane which is perpendicular to the wall and passes through the point of load application.

Poisson's ratio for soils varies from about 0.25 to 0.49, with lower values more typical for granular and stiff cohesive soils and higher values more typical for soft cohesive soils.

Figure 3.11.6.2-2—Horizontal Pressure on a Wall Caused by a Point Load

The horizontal pressure, Δ_{ph} in ksf, resulting from an infinitely long line load parallel to a wall may be taken as:

$$\Delta_{ph} = \frac{4Q}{\pi} \frac{X^2 Z}{R^4} \quad (3.11.6.2-3)$$

where:

Q = load intensity in kip/ft

and all other notation is as defined above and shown in Figure 3.11.6.2-3.

Figure 3.11.6.2-3—Horizontal Pressure on a Wall Caused by an Infinitely Long Line Load Parallel to the Wall

The horizontal pressure distribution, Δ_{ph} in ksf, on a wall resulting from a finite line load perpendicular to a wall may be taken as:

$$\Delta_{ph} = \frac{Q}{\pi Z} \left(\frac{1}{A^3} - \frac{1-2\nu}{A + \frac{Z}{X_2}} - \frac{1}{B^3} + \frac{1-2\nu}{B + \frac{Z}{X_1}} \right) \quad (3.11.6.2-4)$$

in which:

$$A = \sqrt{1 + \left(\frac{Z}{X_2} \right)^2} \quad (3.11.6.2-5)$$

$$B = \sqrt{1 + \left(\frac{Z}{X_1} \right)^2} \quad (3.11.6.2-6)$$

where:

- X_1 = distance from the back of the wall to the start of the line load as specified in Figure 3.11.6.2-4 (ft)
- X_2 = distance between the back of wall and the far end of the finite line load as specified in Figure 3.11.6.2-4 (ft)
- Z = depth from the ground surface to a point on the wall under consideration (ft)
- ν = Poisson's ratio (dim.)
- Q = load intensity (kip/ft)

Figure 3.11.6.2-4—Horizontal Pressure on a Wall Caused by a Finite Line Load Perpendicular to the Wall

3.11.6.3—Strip Loads (*ES*): Flexible Walls

Concentrated dead loads shall be incorporated into the internal and external stability design by using a simplified uniform vertical distribution of 2 vertical to 1 horizontal to determine the vertical component of stress with depth within the reinforced soil mass as specified in Figure 3.11.6.3-1. Concentrated horizontal loads at the top of the wall shall be distributed within the reinforced soil mass as specified in Figure 3.11.6.3-2. If concentrated dead loads are located behind the reinforced soil mass, they shall be distributed in the same way as would be done within the reinforced soil mass.

The vertical stress distributed behind the reinforced zone shall be multiplied by k_a when determining the effect of this surcharge load on external stability. The concentrated horizontal stress distributed behind the wall as specified in Figure 3.11.6.3-2 shall not be multiplied by k_a .

C3.11.6.3

Figures 3.11.6.3-1 and 3.11.6.3-2 are based on the assumption that the wall is relatively free to move laterally (e.g., MSE walls).

Where: D_1 = Effective width of applied load at any depth, calculated as shown above

b_f = Width of applied load. For footings which are eccentrically loaded (e.g., bridge abutment footings), set b_f equal to the equivalent footing width B' by reducing it by $2e'$, where e' is the eccentricity of the footing load (i.e., $b_f - 2e'$).

L = Length of footing

P_v = Load per linear foot of strip footing

P'_v = Load on isolated rectangular footing or point load

Z_2 = depth where effective width intersects back of wall face = $2d - b_f$

d = distance between the centroid of the concentrated vertical load and the back of the wall face.

Assume the increased vertical stress due to the surcharge load has no influence on stresses used to evaluate internal stability if the surcharge load is located behind the reinforced soil mass. For external stability, assume the surcharge has no influence if it is located outside the active zone behind the wall.

Figure 3.11.6.3-1—Distribution of Stress from Concentrated Vertical Load P_v for Internal and External Stability Calculations

e' = eccentricity of load on footing (see Figure 11.10.10.1-1 for example of how to calculate this)

a—Distribution of Stress for Internal Stability Calculations

b—Distribution of Stress for External Stability Calculations

Figure 3.11.6.3-2—Distribution of Stress from Concentrated Horizontal Loads

3.11.6.4—Live Load Surcharge (LS)**3.11.6.4.1—Retaining Walls**

A live load surcharge shall be applied where vehicular load is expected to act on the surface of the backfill within a distance equal to one-half the wall height behind the back face of the wall. If the surcharge is for a highway, the intensity of the load shall be consistent with the provisions of Article 3.6.1.2. If the surcharge is for other than a highway, the Owner shall specify and/or approve appropriate surcharge loads.

The increase in horizontal pressure due to live load surcharge may be estimated as:

$$\Delta_p = k\gamma_s h_{eq} \quad (3.11.6.4.1-1)$$

where:

- Δ_p = constant horizontal earth pressure due to live load surcharge (ksf)
 γ_s = total unit weight of soil (kcf)
 k = coefficient of lateral earth pressure
 h_{eq} = equivalent height of soil for vehicular load (ft)

Equivalent heights of soil, h_{eq} , for highway loadings on abutments and retaining walls may be taken from Tables 3.11.6.4.1-1 and 3.11.6.4.1-2. Linear interpolation shall be used for intermediate wall heights.

The wall height shall be taken as the distance between the surface of the backfill and the bottom of the footing along the pressure surface being considered.

Table 3.11.6.4.1-1—Equivalent Height of Soil for Vehicular Loading on Abutments Perpendicular to Traffic

Abutment Height (ft)	h_{eq} (ft)
5.0	4.0
10.0	3.0
≥ 20.0	2.0

Table 3.11.6.4.1-2—Equivalent Height of Soil for Vehicular Loading on Retaining Walls Parallel to Traffic

Retaining Wall Height (ft)	h_{eq} (ft) Distance from wall backface to edge of traffic	
	0.0 ft	1.0 ft or Further
5.0	5.0	2.0
10.0	3.5	2.0
≥ 20.0	2.0	2.0

The load factor for both vertical and horizontal components of live load surcharge shall be taken as specified in Table 3.4.1-1 for live load surcharge.

C3.11.6.4**C3.11.6.4.1**

The tabulated values for h_{eq} were determined by evaluating the horizontal force against an abutment or wall from the pressure distribution produced by the vehicular live load of Article 3.6.1.2. The pressure distributions were developed from elastic half-space solutions using the following assumptions:

- Vehicle loads are distributed through a two-layer system consisting of pavement and soil subgrade.
- Poisson's ratio for the pavement and subgrade materials are 0.2 and 0.4, respectively.
- Wheel loads were modeled as a finite number of point loads distributed across the tire area to produce an equivalent tire contact stress.
- The process for equating wall moments resulting from the elastic solution with the equivalent surcharge method used a wall height increment of 0.25 ft.

The value of the coefficient of lateral earth pressure k is taken as k_o , specified in Article 3.11.5.2, for walls that do not deflect or move, or k_a , specified in Articles 3.11.5.3, 3.11.5.6 and 3.11.5.7, for walls that deflect or move sufficiently to reach minimum active conditions.

The analyses used to develop Tables 3.11.6.4.1-1 and 3.11.6.4.1-2 are presented in Kim and Barker (1998).

The values for h_{eq} given in Tables 3.11.6.4.1-1 and 3.11.6.4.1-2 are generally greater than the traditional 2.0 ft of earth load historically used in the AASHTO specifications, but less than those prescribed in previous editions (i.e., before 1998) of this specification. The traditional value corresponds to a 20.0-kip single unit truck formerly known as an H10 truck, Peck et al. (1974). This partially explains the increase in h_{eq} in previous editions of this specification. Subsequent analyses, i.e., Kim and Barker (1998), show the importance of the direction of traffic, i.e., parallel for a wall and perpendicular for an abutment on the magnitude of h_{eq} . The magnitude of h_{eq} is greater for an abutment than for a wall due to the proximity and closer spacing of wheel loads to the back of an abutment compared to a wall.

The backface of the wall should be taken as the pressure surface being considered. Refer to Article C11.5.6 for application of surcharge pressures on retaining walls.

Retaining walls have historically been designed considering a lateral live load surcharge pressure to represent the additional load applied by a vehicle located near the wall. This loading was historically applied to culverts as well. However, while a lateral load on a wall increases the overturning moment, such a load on a culvert is transmitted through the culvert, largely through compressive thrust and minimal bending moments. The approaching wheel load replaces the live load surcharge for culverts as specified in Article 3.11.6.4.2.

3.11.6.4.2—Culverts

Concrete box culverts and three-sided flat-topped culverts with a depth of fill less than 2 ft shall be subjected to an approaching wheel load in the form of a lateral soil pressure representing a vehicle approaching the culvert. The pressure shall decrease with increasing depth of fill in accordance with Eq. 3.11.6.4.2-1:

$$\Delta_{AWL} = \frac{700}{h_d} \leq 800 \text{ psf} \quad (3.11.6.4.2-1)$$

where:

Δ_{AWL} = lateral soil pressure at depth h_d (psf)
 h_d = depth of fill at which pressure is calculated (ft)

The calculated pressure shall be applied to both sides of the culvert model.

This load need not be applied to culverts with a depth of fill over the top slab greater than 2 ft nor to concrete culverts with round tops or metal, thermoplastic or fiberglass culverts.

3.11.6.5—Reduction of Surcharge

If the vehicular loading is transmitted through a structural slab, which is also supported by means other than earth, a corresponding reduction in the surcharge loads may be permitted.

3.11.7—Reduction Due to Earth Pressure

For culverts and bridges and their components where earth pressure may reduce effects caused by other loads and forces, such reduction shall be limited to the extent earth pressure can be expected to be permanently present. In lieu of more precise information, a 50 percent reduction may be used, but need not be combined with the minimum load factor specified in Table 3.4.1-2.

3.11.8—Drag Load and Downdrag

Possible downdrag of piles or drilled shafts shall be evaluated where:

- Sites are underlain by compressible material such as clays, silts or organic soils;
- Fill will be or has recently been placed adjacent to the piles or shafts, such as is frequently the case for bridge approach fills;
- The groundwater is substantially lowered; or
- Liquefaction of loose sandy soil can occur.

When the potential for downdrag exists and the drag load is not reduced by preloading the soil to minimize downward movements or other mitigating measures, the pile or shaft shall be designed to resist the induced drag load.

C3.11.6.5

This Article relates primarily to approach slabs which are supported at one edge by the backwall of an abutment, thus transmitting load directly thereto.

C3.11.7

This provision is intended to refine the traditional approach in which the earth pressure is reduced by 50 percent in order to obtain maximum positive moment in top slab of culverts and frames. It permits obtaining more precise estimates of force effects where earth pressures are present.

C3.11.8

Drag load can be caused by soil settlement due to surcharge loads from new fill applied after deep foundations are installed, such as an approach embankment as shown in Figure C3.11.8-1. Consolidation can also occur due to recent lowering of the groundwater level or other factors as shown in Figure C3.11.8-2.

Consideration shall be given to eliminating the potential for drag loads with embankment surcharge loads, ground improvement methods, and/or vertical drainage and settlement monitoring measurements.

For Extreme Event I limit state, drag load induced by liquefaction settlement shall be applied to the pile or shaft in combination with the other loads included within that load group. Liquefaction-induced drag load shall not be combined with drag load induced by consolidation settlements.

For drag load applied to pile or shaft groups, group effects shall be evaluated.

Figure C3.11.8-1—Common Downdrag Situation Due to Fill Weight (Hannigan et al., 2016)

Figure C3.11.8-2—Common Downdrag Situation Due to Reasons Other than Surcharge Loads from New Fill

Methods for reducing static downdrag potential include preloading, waiting periods, and ground improvement methods. The procedure for designing a preload is presented in Samtani and Nowatzki (2006).

Post-liquefaction settlement can also cause drag load. Methods for mitigating liquefaction-induced downdrag are presented in Kavazanjian et al. (2011).

The application of drag load to pile or shaft groups can be complex. If the pile or shaft cap is near or below the fill material causing consolidation settlement of the underlying soft soil, the cap will prevent transfer of stresses adequate to produce settlement of the soil inside the pile or shaft group. The drag load applied in this case is the frictional force around the exterior of the pile or shaft group and along the sides of the pile or shaft cap, if any. If the cap is located high up in the fill causing consolidation stresses or if the piles or shafts are used as individual columns to support the structure above ground, the drag load on each individual pile or shaft will control the magnitude of the load. If group effects are likely, the drag load calculated using the group perimeter shear force should be determined in addition to the sum of the drag load for each individual

Drag load on piles or drilled shafts should be determined as follows:

Step 1—Characterize the soil stratigraphy and material properties for computing settlement using the procedures in Article 10.4.

Step 2—Calculate settlement for the soil layers along the length of the pile or shaft using the procedures in Article 10.6.2.4.

Step 3—Determine the length of pile or shaft that will be subject to drag load.

Step 4—Determine the magnitude of the drag load, DR , using the neutral plane method.

pile or shaft. The greater of the two calculations should be used for design.

The skin friction used to estimate drag load due to liquefaction settlement should be conservatively assumed to be equal to the residual soil strength in the liquefiable layers, and nonliquefied skin friction in nonliquefiable layers.

The step-by-step procedure for analyzing downdrag is presented in detail in Hannigan et al. (2016).

The stress increases in each soil layer due to embankment loading can be estimated using the procedures in Hannigan et al. (2016) or Samtani and Nowatzki (2006).

If the settlement is due to liquefaction, the Tokimatsu and Seed (1987) or the Ishihara and Yoshimine (1992) procedures can be used to estimate settlement.

Previously, the downdrag design approach specified that drag load was resisted at the geotechnical strength limit state. However, as axial compression load approaches the nominal geotechnical resistance, all skin resistance is positive (acting upward) and no drag force exists. Hence, drag load does not affect the geotechnical strength limit state.

The load in a deep foundation and associated pile or shaft settlement are governed by the pile or shaft geometry, foundation and soil material properties, and load distribution. Structural top loading and drag load above the neutral plane are resisted by a combination of side and tip resistance below the neutral plane.

The loading and unloading behavior along the pile or shaft is displacement dependent. If performing the analysis manually using graphical constructions or similar methods, estimates of the neutral plane depth, ground settlement, foundation movement, and mobilized tip resistance with respect to pile or shaft tip penetration are required. Simplifying assumptions, such as fully mobilized side resistance, result in less accurate results than obtained with more rigorous methods.

Performing a neutral plane analysis requires both soil and foundation information including information about stratigraphy, soil type, strength, and stiffness with depth, pile or shaft material, and dimensions.

While there are manual methods presented in Hannigan et al. (2016) to approximate the soil settlement, pile or shaft movement, neutral plane location, and drag load, the neutral plane method is best performed by applying t - z and q - z relationships. When software programs or spreadsheets using semi-empirical curves or experimentally fitted models and iterative approaches are employed, assumptions about side and tip resistance mobilization are embedded in the selected t - z and q - z curves. The location of the neutral plane, the maximum additional drag load for evaluation of structural strength, and pile or shaft settlement are computed based on the input parameters. For extreme events, the soil stratigraphy and material property input values must be adjusted to represent the conditions at the appropriate limit state.

A neutral plane t - z/q analysis is the axial analogy to the lateral p - y analysis, which is similarly based on load and deformation relationships. The level of effort and information required for both types of analysis are similar and should be performed using spreadsheets or computer programs for both accuracy and efficiency.

The recommended approach for evaluating downdrag is based on the neutral plane method developed by Fellenius (1989), modified by Siegel et al. (2013), and detailed in Hannigan et al. (2016).

3.12—FORCE EFFECTS DUE TO SUPERIMPOSED DEFORMATIONS: TU , TG , SH , CR , SE , PS

3.12.1—General

Internal force effects in a component due to creep and shrinkage shall be considered. The effect of a temperature gradient should be included where appropriate. Force effects resulting from resisting component deformation, displacement of points of load application, and support movements shall be included in the analysis.

3.12.2—Uniform Temperature

The design thermal movement associated with a uniform temperature change may be calculated using Procedure A or Procedure B below. Either Procedure A or Procedure B may be employed for concrete deck bridges having concrete or steel girders. Procedure A shall be employed for all other bridge types.

3.12.2.1—Temperature Range for Procedure A

The ranges of temperature shall be as specified in Table 3.12.2.1-1. The difference between the extended lower or upper boundary and the base construction temperature assumed in the design shall be used to calculate thermal deformation effects.

The minimum and maximum temperatures specified in Table 3.12.2.1-1 shall be taken as $T_{MinDesign}$ and $T_{MaxDesign}$, respectively, in Eq. 3.12.2.3-1.

C3.12.2.1

Procedure A is the historic method that has been used for bridge design.

For these Specifications, a moderate climate may be determined by the number of freezing days per yr. If the number of freezing days is less than 14, the climate is considered to be moderate. Freezing days are days when the average temperature is less than 32°F.

Although temperature changes in a bridge do not occur uniformly, bridges generally are designed for an assumed uniform temperature change. The orientation of bearing guides and the freedom of bearing movement is important. Sharp curvature and sharply skewed supports can cause excessive lateral thermal forces at supports if only tangential movement is permitted. Wide bridges are particularly prone to large lateral thermal forces because the bridge expands radially as well as longitudinally.

Table 3.12.2.1-1—Procedure A Temperature Ranges

Climate	Steel or Aluminum	Concrete	Wood
Moderate	0° to 120°F	10° to 80°F	10° to 75°F
Cold	−30° to 120°F	0° to 80°F	0° to 75°F

3.12.2.2—Temperature Range for Procedure B

The temperature range shall be defined as the difference between the maximum design temperature, $T_{MaxDesign}$, and the minimum design temperature, $T_{MinDesign}$. For all concrete girder bridges with concrete decks, $T_{MaxDesign}$ shall be determined from the contours of Figure 3.12.2.2-1 and $T_{MinDesign}$ shall be determined from the contours of Figure 3.12.2.2-2. For steel girder bridges with concrete decks, $T_{MaxDesign}$ shall be determined from the contours of Figure 3.12.2.2-3 and $T_{MinDesign}$ shall be determined from the contours of Figure 3.12.2.2-4.

C3.12.2.2

The Procedure B design was developed on the basis of Roeder (2002).

Procedure B is a calibrated procedure and does not cover all bridge types. The temperatures provided in the maps of Figures 3.12.2.2-1 to 3.12.2.2-4 are extreme bridge design temperatures for an average history of 70 yr with a minimum of 60 yr of data for locations throughout the U.S.

The design values for locations between contours should be determined by linear interpolation. As an alternative method, the largest adjacent contour may be used to define $T_{MaxDesign}$ and the smallest adjacent contour may be used to define $T_{MinDesign}$. Both the minimum and maximum design temperatures should be noted on the drawings for the girders, expansion joints, and bearings.

Figure 3.12.2.2-1—Contour Maps for $T_{MaxDesign}$ for Concrete Girder Bridges with Concrete Decks

Figure 3.12.2.2-2—Contour Maps for $T_{MinDesign}$ for Concrete Girder Bridges with Concrete Decks

Figure 3.12.2.2-3—Contour Maps for $T_{MaxDesign}$ for Steel Girder Bridges with Concrete DecksFigure 3.12.2.2-4—Contour Maps for $T_{MinDesign}$ for Steel Girder Bridges with Concrete Decks

3.12.2.3—Design Thermal Movements

The design thermal movement range, Δ_T , shall depend upon the extreme bridge design temperatures defined in Article 3.12.2.1 or 3.12.2.2, and be determined as:

$$\Delta_T = \alpha L (T_{MaxDesign} - T_{MinDesign}) \quad (3.12.2.3-1)$$

where:

L = expansion length (in.)

α = coefficient of thermal expansion (in./in./°F)

3.12.3—Temperature Gradient

For the purpose of this Article, the country shall be subdivided into zones as indicated in Figure 3.12.3-1. Positive temperature values for the zones shall be taken as specified for various deck surface conditions in Table 3.12.3-1. Negative temperature values shall be obtained by multiplying the values specified in Table 3.12.3-1 by -0.30 for plain concrete decks and -0.20 for decks with an asphalt overlay.

The vertical temperature gradient in concrete and steel superstructures with concrete decks may be taken as shown in Figure 3.12.3-2.

Dimension A in Figure 3.12.3-2 shall be taken as:

- For concrete superstructures that are 16.0 in. or more in depth—12.0 in.
- For concrete sections shallower than 16.0 in.—4.0 in. less than the actual depth
- For steel superstructures—12.0 in. and the distance t shall be taken as the depth of the concrete deck

Temperature value T_3 shall be taken as 0.0 degrees F, unless a site-specific study is made to determine an appropriate value, but it shall not exceed 5 degrees F.

Where temperature gradient is considered, internal stresses and structure deformations due to both positive and negative temperature gradients may be determined in accordance with the provisions of Article 4.6.6.

Table 3.12.3-1—Basis for Temperature Gradients

Zone	T_1 (°F)	T_2 (°F)
1	54	14
2	46	12
3	41	11
4	38	9

Figure 3.12.3-1—Solar Radiation Zones for the United States

C3.12.3

Temperature gradient is included in various load combinations in Table 3.4.1-1. This does not mean that it need be investigated for all types of structures. If experience has shown that neglecting temperature gradient in the design of a given type of structure has not lead to structural distress, the Owner may choose to exclude temperature gradient. Multibeam bridges are an example of a type of structure for which judgment and past experience should be considered.

Redistribution of reactive loads, both longitudinally and transversely, should also be calculated and considered in the design of the bearings and substructures.

The temperature gradient given herein is a modification of that proposed in Imbsen et al. (1985), which was based on studies of concrete superstructures. The addition for steel superstructures is patterned after the temperature gradient for that type of bridge in the Australian bridge specifications (AUSTROADS, 1992).

The data in Table 3.12.3-1 does not make a distinction regarding the presence or lack of an asphaltic overlay on decks. Field measurements have yielded apparently different indications concerning the effect of asphalt as an insulator or as a contributor (Spring, 1997). Therefore, any possible insulating qualities have been ignored herein.

The temperatures given in Table 3.12.3-1 form the basis for calculating the change in temperature with depth in the cross-section, not absolute temperature.

Figure 3.12.3-2—Positive Vertical Temperature Gradient in Concrete and Steel Superstructures

3.12.4—Differential Shrinkage

Where appropriate, differential shrinkage strains between concretes of different age and composition, and between concrete and steel or wood, shall be determined in accordance with the provisions of Section 5.

3.12.5—Creep

Creep strains for concrete and wood shall be in accordance with the provisions of Section 5 and Section 8, respectively. In determining force effects and deformations due to creep, dependence on time and changes in compressive stresses shall be taken into account.

3.12.6—Settlement

Force effects due to extreme values of differential settlements among substructures and within individual substructure units shall be considered. Estimates of settlement for individual substructure units may be made in accordance with the provisions in Article 10.7.2.3.

3.12.7—Secondary Forces from Post-Tensioning, *PS*

The application of post-tensioning forces on a continuous structure produces reactions at the supports and internal forces that are collectively called secondary forces, which shall be considered where applicable.

3.13—FRICTION FORCES: *FR*

Forces due to friction shall be established on the basis of extreme values of the friction coefficient between the

C3.12.4

The Designer may specify timing and sequence of construction in order to minimize stresses due to differential shrinkage between components.

C3.12.5

Traditionally, only creep of concrete is considered. Creep of wood is addressed only because it applies to prestressed wood decks.

C3.12.6

Force effects due to settlement may be reduced by considering creep. Analysis for the load combinations in Tables 3.4.1-1 and 3.4.1-2 which include settlement should be repeated for settlement of each possible substructure unit settling individually, as well as combinations of substructure units settling, that could create critical force effects in the structure.

C3.12.7

In frame analysis software, secondary forces are generally obtained by subtracting the primary prestress forces from the total prestressing.

C3.13

Low and high friction coefficients may be obtained from standard textbooks. If so warranted, the values may

sliding surfaces. Where appropriate, the effect of moisture and possible degradation or contamination of sliding or rotating surfaces upon the friction coefficient shall be considered.

3.14—VESSEL COLLISION: *CV*

3.14.1—General

The provisions of this Article apply to the accidental collision between a vessel and a bridge. These provisions may be revised as stated in Article 3.14.16 to account for intentional collisions.

All bridge components in a navigable waterway crossing, located in design water depths not less than 2.0 ft, shall be designed for vessel impact.

The minimum design impact load for substructure design shall be determined using an empty hopper barge drifting at a velocity equal to the yearly mean current for the waterway location. The design barge shall be a single 35.0-ft × 195-ft barge, with an empty displacement of 200 tons, unless approved otherwise by the Owner.

Where bridges span deep draft waterways and are not sufficiently high to preclude contact with the vessel, the minimum superstructure design impact may be taken to be the mast collision impact load specified in Article 3.14.10.3.

In navigable waterways where vessel collision is anticipated, structures shall be:

- designed to resist vessel collision forces, and/or
- adequately protected by fenders, dolphins, berms, islands, or other sacrifice-able devices.

In determining vessel collision loads, consideration shall be given to the relationship of the bridge to:

- waterway geometry,
- size, type, loading condition, and frequency of vessels using the waterway,
- available water depth,

be determined by physical tests, especially if the surfaces are expected to be roughened in service.

C3.14.1

Intentional collision between a vessel and a bridge may be considered when conducting security studies.

The determination of the navigability of a waterway is usually made by the U.S. Coast Guard.

The requirements herein have been adapted from the AASHTO *Guide Specifications and Commentary for Vessel Collision Design of Highway Bridges* (1991) using the Method II risk acceptance alternative, and modified for the second edition (2009). The 1991 edition of the Guide Specifications required the use of a single vessel length overall (*LOA*) selected in accordance with the Method I criteria for use in estimating the geometric probability and impact speed to represent all vessel classifications. This was a conservative simplification applied to reduce the amount of effort required in the analysis. With the introduction of personal computers and programming, the simplification can be lifted and *AF* can be quickly obtained for each design vessel, which was originally envisioned. The end result is a more accurate model for the vessel collision study as well as more informative conclusions about the vessel fleet and associated probabilities of collision.

Another source of information has been the proceedings of an international colloquium, *Ship Collisions with Bridges and Offshore Structures* (IABSE, 1983).

Barges are categorized by ton = 2,000 lbs. and ships by tonne = 2,205 lbs.

The deadweight tonnage (DWT) of a ship is the weight of the cargo, fuel, water, and stores. The DWT is only a portion of the total vessel weight, but it gives a general estimation of the ship size.

A minimum impact requirement from an empty barge drifting in all waterways and the mast impact of a drifting ship in deep draft waterways is specified because of the high frequency of occurrences of such collision accidents in United States waterways.

The intent of the vessel collision provisions is to minimize the risk of catastrophic failure of bridges crossing navigable waterways due to collisions by aberrant vessels. The collision impact forces represent a probabilistically based, worst-case, head-on collision, with the vessel moving in a forward direction at a relatively high velocity. The requirements are applicable to steel-hulled merchant ships larger than 1,000 DWT and to inland waterway barges.

The channel layout and geometry can affect the navigation conditions, the largest vessel size that can use the waterway and the loading condition and the speed of vessels approaching a bridge. The presence of bends, intersections with other waterways, and the presence of

- vessel speed and direction, and
- the structural response of the bridge to collision.

Evaluation of the following vessel collision events shall be combined with foundation conditions due to scour as specified in Article 2.6.4.4.4:

- Case A—A drifting empty barge breaking loose from its moorings and striking the bridge.
- Case B—A ship or barge tow striking the bridge while transiting the navigation channel under typical waterway conditions.

other bridge crossings near the bridge increase the probability of accidents. The vessel transit paths in the waterway in relation to the navigation channel and the bridge piers can affect the risk of aberrant vessels hitting the piers and the exposed portions of the superstructure.

The water level and the loading conditions of vessels influence the location on the pier where vessel impact loads are applied, and the susceptibility of the superstructure to vessel hits. The water depth plays a critical role in the accessibility of vessels to piers and spans outside the navigation channel. The water depth at the pier should not include short-term scour. In addition, the water depth should not just be evaluated at the specific pier location itself, but also at locations upstream and downstream of the pier—which may be shallower and would potentially block certain deeper draft vessels from hitting the pier. In waterways with large water stage fluctuations, the water level used can have a significant effect on the structural requirements for the pier and/or pier protection design.

The maneuverability of ships is reduced by the low underkeel clearance typical in inland waterways. Shallow underkeel clearance can also affect the hydrodynamic forces during a collision increasing the collision energy, especially in the transverse direction. In addition, ships riding in ballast can be greatly affected by winds and currents. When under ballast, vessels are susceptible to wind gusts that could push them into the bridge.

It is very difficult to control and steer barge tows, especially near bends and in waterways with high stream velocities and cross currents. In maneuvering a bend, tows experience a sliding effect in a direction opposite to the direction of the turn, due to inertia forces which are often coupled with the current flow. Bridges located in a high velocity waterway and near a bend in the channel will probably be hit by barges at frequent intervals.

3.14.2—Owner's Responsibility

The Owner shall establish and/or approve the bridge operational classification, the vessel traffic density in the waterway, and the design velocity of vessels for the bridge. The Owner shall specify or approve the degree of damage that the bridge components, including protective systems, are allowed to sustain.

3.14.3—Operational Classification

For the purpose of Article 3.14, an operational classification, either “critical or essential” or “typical,” shall be determined for all bridges located in navigable waterways. Critical bridges shall continue to function after an impact, the probability of which is smaller than regular bridges.

C3.14.2

Pier protection systems may also be warranted for bridges over navigable channels transversed only by pleasure boats or small commercial vessels. For such locations, dolphins and fender systems are commonly used to protect the pier and to minimize the hazards of passage under the bridge for the vessels using the waterway.

C3.14.3

This Article implies that a critical or essential bridge may be damaged to an extent acceptable to the Owner, as specified in Article 3.14.2, but should not collapse and should remain serviceable, even though repairs are needed.

3.14.4—Design Vessel

A design vessel for each pier or span component shall be selected, such that the estimated annual frequency of collapse computed in accordance with Article 3.14.5, due to vessels not smaller than the design vessel, is less than the acceptance criterion for the component.

The design vessels shall be selected on the basis of the bridge operational classification and the vessel, bridge, and waterway characteristics.

C3.14.4

An analysis of the annual frequency of collapse is performed for each pier or span component exposed to collision. From this analysis, a design vessel and its associated collision loads can be determined for each pier or span component. The design vessel size and impact loads can vary greatly among the components of the same structure, depending upon the waterway geometry, available water depth, bridge geometry, and vessel traffic characteristics.

The design vessel is selected using a probability-based analysis procedure in which the predicted annual frequency of bridge collapse, AF , is compared to an acceptance criterion. The analysis procedure is an iterative process in which a trial design vessel is selected for a bridge component and a resulting AF is computed using the characteristics of waterway, bridge, and vessel fleet. This AF is compared to the acceptance criterion, and revisions to the analysis variables are made as necessary to achieve compliance. The primary variables that the Designer can usually alter include the:

- location of the bridge in the waterway;
- location and clearances of bridge pier and span components;
- resistance of piers and superstructures; and
- use of protective systems to either reduce or eliminate the collision forces.

3.14.5—Annual Frequency of Collapse

The annual frequency of a bridge component collapse shall be taken as:

$$AF = (N)(PA)(PG)(PC)(PF) \quad (3.14.5-1)$$

where:

- AF = annual frequency of bridge component collapse due to vessel collision
 N = the annual number of vessels, classified by type, size, and loading condition, that utilize the channel
 PA = the probability of vessel aberrancy
 PG = the geometric probability of a collision between an aberrant vessel and a bridge pier or span
 PC = the probability of bridge collapse due to a collision with an aberrant vessel
 PF = adjustment factor to account for potential protection of the piers from vessel collision due to upstream or downstream land masses or other structures that block the vessel

AF shall be computed for each bridge component and vessel classification. The annual frequency

C3.14.5

Various types of risk assessment models have been developed for vessel collision with bridges by researchers worldwide (IABSE, 1983) (Modjeski and Masters, 1984) (Prucz, 1987) (Larsen, 1993). Practically all of these models are based on a form similar to Eq. 3.14.5-1, which is used to compute the annual frequency of bridge collapse, AF , associated with a particular bridge component.

The inverse of the annual frequency of collapse, $1/AF$, is equal to the return period in yr. The summation of AF s computed over all of the vessel classification intervals for a specific component equals the annual frequency of collapse of the component.

of collapse for the total bridge shall be taken as the sum of all component AF s.

For critical or essential bridges, the maximum annual frequency of collapse, AF , for the whole bridge, shall be taken as 0.0001.

For typical bridges, the maximum annual frequency of collapse, AF , for the total bridge, shall be taken as 0.001.

For waterways with widths less than 6.0 times the length overall of the design vessel, LOA , the acceptance criterion for the annual frequency of collapse for each pier and superstructure component shall be determined by distributing the total bridge acceptance criterion, AF , over the number of pier and span components located in the waterway.

For wide waterways with widths greater than 6.0 times LOA , the acceptance criterion for the annual frequency of collapse for each pier and span component shall be determined by distributing the total bridge acceptance criterion over the number of pier and superstructure components located within the distance 3.0 times LOA on each side of the inbound and outbound vessel transit centerline paths.

3.14.5.1—Vessel Frequency Distribution

The number of vessels, N , based on size, type, and loading condition and available water depth shall be developed for each pier and span component to be evaluated. Depending on waterway conditions, a differentiation between the number and loading condition of vessels transiting inbound and outbound shall be considered.

Risk can be defined as the potential realization of unwanted consequences of an event. Both a probability of occurrence of an event and the magnitude of its consequences are involved. Defining an acceptable level of risk is a value-oriented process and is by nature subjective (Rowe, 1977).

Based on historical collision data, the primary area of concern for vessel impact is the central portion of the bridge near the navigation channel. The limits of this area extend to a distance of 3.0 times LOA on each side of the inbound and outbound vessel transit path centerlines. For most bridges, these vessel transit path centerlines coincide with the centerline of the navigable channel. Where two-way vessel traffic exists under the bridge, the vessel transit path centerline of the inbound and outbound vessels should be taken as the centerline of each half of the channel, respectively.

The distribution of the AF acceptance criterion among the exposed pier and span components is based on the Designer's judgment. One method is to equally spread the acceptable risk among all the components. This method is usually not desirable because it fails to take into account the importance and higher cost of most main span components. The preferred method is to apportion the risk to each pier and span component on the basis of its percentage value to the replacement cost of the structure in the central analysis area.

C3.14.5.1

In developing the design vessel distribution, the Designer should first establish the number and characteristics of the vessels using the navigable waterway or channel under the bridge. Because the water depth limits the size of vessel that could strike a bridge component, the navigable channel vessel frequency data can be modified, as required, on the basis of the water depth at each bridge component to determine the number and characteristics of the vessels that could strike the pier or span component being analyzed. Thus, each component could have a different value of N .

Vessel characteristics necessary to conduct the analysis include:

- Type, e.g., ship or barge;
- Size based on the vessel's DWT;
- Inbound and outbound operating characteristics;
- Loading condition, i.e., loaded, partly loaded, ballasted, or empty;
- Length overall, LOA ;
- Width or beam, B_M ;
- Draft associated with each loading condition;
- Bow depth, D_B ;
- Bow shape;
- Displacement tonnage, W ;
- Vertical clearances; and
- Number of transits under the bridge each year.

Sources for the vessel data and typical ship and barge characteristics are included in the *AASHTO Guide Specifications and Commentary for Vessel Collision Design of Highway Bridges* (2009).

The Designer should use judgment in developing a distribution of the vessel frequency data based on discrete groupings or categories of vessel size by DWT. It is recommended that the DWT intervals used in developing the vessel distribution not exceed 20,000 DWT for vessels smaller than 100,000 DWT, and not exceeding 50,000 DWT for ships larger than 100,000 DWT.

3.14.5.2—Probability of Aberrancy

3.14.5.2.1—General

The probability of vessel aberrancy, PA , may be determined by the statistical or the approximate method.

C3.14.5.2.1

The probability of aberrancy is mainly related to the navigation conditions at the bridge site. Vessel traffic regulations, vessel traffic management systems and aids to navigation can improve the navigation conditions and reduce the probability of aberrancy.

The probability of aberrancy, PA , sometimes referred to as the causation probability, is a measure of the risk that a vessel is in trouble as a result of pilot error, adverse environmental conditions, or mechanical failure.

An evaluation of accident statistics indicates that human error and adverse environmental conditions, not mechanical failures, are the primary reasons for accidents. In the United States, an estimated 60 percent to 85 percent of all vessel accidents have been attributed to human error.

3.14.5.2.2—Statistical Method

The probability of aberrancy may be computed on the basis of a statistical analysis of historical data on vessel collisions, rammings, and groundings in the waterway and on the number of vessels transiting the waterway during the period of accident reporting.

C3.14.5.2.2

The most accurate procedure for determining PA is to compute it using long-term vessel accident statistics in the waterway and data on the frequency of ship/barge traffic in the waterway during the same period of time (Larsen 1983). Data from ship simulation studies and radar analysis of vessel movements in the waterway have also been used to estimate PA . Based on historical data, it has been determined that the aberrancy rate for barges is usually two to three times that measured for ships in the same waterway.

3.14.5.2.3—Approximate Method

The probability of aberrancy may be taken as:

$$PA = (BR)(R_B)(R_C)(R_{XC})(R_D) \quad (3.14.5.2.3-1)$$

where:

PA = probability of aberrancy
 BR = aberrancy base rate

C3.14.5.2.3

Because the determination of PA based on actual accident data in the waterway is often a difficult and time-consuming process, an alternative method for estimating PA was established during the development of the *AASHTO Guide Specification and Commentary on Vessel Collision Design of Highway Bridges*. The equations in this Article are empirical relationships based on historical accident data. The predicted PA value using these

- R_B = correction factor for bridge location
 R_C = correction factor for current acting parallel to vessel transit path
 R_{XC} = correction factor for cross-currents acting perpendicular to vessel transit path
 R_D = correction factor for vessel traffic density

The base rate, BR , of aberrancy shall be taken as:

- For ships:

$$BR = 0.6 \times 10^{-4}$$

- For barges:

$$BR = 1.2 \times 10^{-4}$$

The correction factor for bridge location, R_B , based on the relative location of the bridge in either of three waterway regions, as shown in Figure 3.14.5.2.3-1, shall be taken as:

- For straight regions:

$$R_B = 1.0 \quad (3.14.5.2.3-2)$$

- For transition regions:

$$R_B = \left(1 + \frac{\theta}{90^\circ} \right) \quad (3.14.5.2.3-3)$$

- For turn/bend regions:

$$R_B = \left(1 + \frac{\theta}{45^\circ} \right) \quad (3.14.5.2.3-4)$$

where:

θ = angle of the turn or bend, specified in Figure 3.14.5.2.3-1 (degrees)

The correction factor, R_C , for currents acting parallel to the vessel transit path in the waterway shall be taken as:

$$R_C = \left(1 + \frac{V_C}{10} \right) \quad (3.14.5.2.3-5)$$

where:

V_C = current velocity component parallel to the vessel transit path (knots)

The correction factor, R_{XC} , for cross-currents acting perpendicular to the vessel transit path in the waterway shall be taken as:

$$R_{XC} = (1 + V_{XC}) \quad (3.14.5.2.3-6)$$

equations and the values determined from accident statistics are generally in agreement, although exceptions do occur.

It should be noted that the procedure for computing PA using Eq. 3.14.5.2.3-1 should not be considered to be either rigorous or exhaustive. Several influences, such as wind, visibility conditions, navigation aids, pilotage, etc., were not directly included in the method because their effects were difficult to quantify. These influences have been indirectly included because the empirical equations were developed from accident data in which these factors had a part.

It is anticipated that future research will provide a better understanding of the probability of aberrancy and how to accurately estimate its value. The implementation of advanced vessel traffic control systems using automated surveillance and warning technology should significantly reduce the probability of aberrancy in navigable waterways.

where:

V_{XC} = current velocity component perpendicular to the vessel transit path (knots)

a. Turn in Channel

b. Bend in Channel

Figure 3.14.5.2.3-1—Waterway Regions for Bridge Location

The correction factor for vessel traffic density, R_D , shall be selected on the basis of the ship/barge traffic density level in the waterway in the immediate vicinity of the bridge defined as:

- Low density—vessels rarely meet, pass, or overtake each other in the immediate vicinity of the bridge:

$$R_D = 1.0 \quad (3.14.5.2.3-7)$$

- Average density—vessels occasionally meet, pass, or overtake each other in the immediate vicinity of the bridge:

$$R_D = 1.3 \quad (3.14.5.2.3-8)$$

- High density—vessels routinely meet, pass, or overtake each other in the immediate vicinity of the bridge:

$$R_D = 1.6 \quad (3.14.5.2.3-9)$$

3.14.5.3—Geometric Probability

A normal distribution may be utilized to model the sailing path of an aberrant vessel near the bridge. The geometric probability, PG , shall be taken as the area under the normal distribution bounded by the pier width and the width of the vessel on each side of the pier, as specified in Figure 3.14.5.3-1. The standard deviation, σ , of the normal distribution shall be assumed to be equal to the length overall, LOA , of the design vessel selected in accordance with Article 3.14.4.

The location of the mean of the standard distribution shall be taken at the centerline of the vessel transit path. PG shall be determined based on the width, B_M , of each vessel classification category, or it may be determined for all classification intervals using the B_M of the design vessel selected in accordance with Article 3.14.4.

Figure 3.14.5.3-1—Geometric Probability of Pier Collision

C3.14.5.3

The geometric probability, PG , is defined as the conditional probability that a vessel will hit a bridge pier or superstructure component, given that it has lost control, i.e., it is aberrant, in the vicinity of the bridge. The probability of occurrence depends on the following factors:

- geometry of waterway;
- water depths of waterway;
- location of bridge piers;
- span clearances;
- sailing path of vessel;
- maneuvering characteristics of vessel;
- location, heading, and velocity of vessel;
- rudder angle at time of failure;
- environmental conditions;
- width, length, and shape of vessel; and
- vessel draft.

The horizontal clearance of the navigation span has a significant impact on the risk of vessel collision with the main piers. Analysis of past collision accidents has shown that fixed bridges with a main span less than two to three times the design vessel length or less than two times the channel width are particularly vulnerable to vessel collision.

Various geometric probability models, some based on simulation studies, have been recommended and used on different bridge projects and for the development of general design provisions. Descriptions of these models may be found in IABSE (1983), Modjeski and Masters (1984), Prucz (1987), and Larsen (1993). The method used to determine PG herein is similar to that proposed by Knott et al. (1985). The use of a normal distribution is based on historical ship/bridge accident data. It is recommended that $\sigma = LOA$ of the design vessel for computing PG , and that bridge components located beyond 3σ from the centerline of the vessel transit path not be included in the analysis, other than the minimum impact requirement of Article 3.14.1.

The accident data used to develop the PG methodology primarily represents ships. Although barge accidents occur relatively frequently in United States waterways, there have been little published research findings concerning the distribution of barge accidents over a waterway. Until such data and research become available, it is recommended that the same $\sigma = LOA$ developed for ships be applied to barges with the barge LOA equal to the total length of the barge tow, including the towboat.

3.14.5.4—Probability of Collapse

The probability of bridge collapse, PC , based on the ratio of the ultimate lateral resistance of the pier, H_P , and span, H_S , to the vessel impact force, P , shall be taken as:

- If $0.0 \leq H/P < 0.1$, then

$$PC = 0.1 + 9 \left(0.1 - \frac{H}{P} \right) \quad (3.14.5.4-1)$$

- If $0.1 \leq H/P < 1.0$, then

$$PC = 0.111 \left(1 - \frac{H}{P} \right) \quad (3.14.5.4-2)$$

- If $H/P \geq 1.0$, then

$$PC = 0.0 \quad (3.14.5.4-3)$$

where:

PC = probability of collapse

H = resistance of bridge component to a horizontal force expressed as pier resistance, H_P , or superstructure resistance, H_S (kip)

P = vessel impact force, P_S , P_{BH} , P_{DH} , or P_{MT} , specified in Articles 3.14.8, 3.14.10.1, 3.14.10.2, and 3.14.10.3, respectively (kip)

C3.14.5.4

The probability that the bridge will collapse once it has been struck by an aberrant vessel, PC , is complex and is a function of the vessel size, type, configuration, speed, direction, and mass. It is also dependent on the nature of the collision and stiffness/strength characteristic of the bridge pier and superstructure to resist the collision impact loads.

The methodology for estimating PC was developed by Cowiconsult (1987) from studies performed by Fujii and Shiobara (1978) using Japanese historical damage data on vessels colliding at sea. The damage to bridge piers is based on ship damage data because accurate damage data for collision with bridges is relatively scarce.

Figure C3.14.5.4-1 is a plot of the probability of collapse relationships. From this figure, the following results are evident:

- Where the pier or superstructure impact resistance exceeds the vessel collision impact force of the design vessel, the bridge collapse probability becomes 0.0.
- Where the pier or superstructure impact resistance is in the range 10–100 percent of the collision force of the design vessel, the bridge collapse probability varies linearly between 0.0 and 0.10.
- Where the pier or superstructure impact resistance is below ten percent of the collision force, the bridge collapse probability varies linearly between 0.10 and 1.0.

Figure C3.14.5.4-1—Probability of Collapse Distribution

3.14.5.5 Protection Factor

The protection factor, PF , shall be computed as:

$$PF = 1 - (\text{percent Protection Provided}/100) \quad (3.14.5.5-1)$$

If no protection of the pier exists, then $PF = 1.0$. If the pier is 100 percent protected, then $PF = 0.0$. If the pier protection (for example, a dolphin system) provides 70 percent protection, then PF would be equal to 0.3.

C3.14.5.5

The purpose of the protection factor, PF , is to adjust the annual frequency of collapse, AF , for full or partial protection of selected bridge piers from vessel collisions such as:

- dolphins, islands, etc.,
- existing site conditions such as a parallel bridge protecting a bridge from impacts in one direction,

Values for PF may vary from pier to pier and may vary depending on the direction of the vessel traffic (i.e., vessel traffic moving inbound versus traffic moving outbound).

- a feature of the waterway (such as a peninsula extending out on one side of the bridge) that may block vessels from hitting bridge piers, or
- a wharf structure near the bridge that may block vessels from a certain direction.

The recommended procedure for estimating values for PF is shown in Figure C3.14.5.5-1. It illustrates a simple model developed to estimate the effectiveness of dolphin protection on a bridge pier.

- θ = Protection angle provided by dolphin
- D = Diameter of dolphin (ft)
- B = Beam (width) of vessel (ft)
- L = Distance of dolphin from pier (ft)
- D_E = Effective dolphin diameter (ft)

a. Plan of Dolphin Protection.

b. Normal Distribution of Vessel Collision Trajectories Around Bridge Pier (σ assumed = 30°).

Figure C3.14.5.5-1—Illustrative Model of the Protection Factor (PF) of Dolphin Protection around a Bridge Pier

3.14.6—Design Collision Velocity

C3.14.6

The design collision velocity may be determined as specified in Figure 3.14.6-1, for which:

A triangular distribution of collision impact velocity across the length of the bridge and centered on the

- V = design impact velocity (ft/s)
 V_T = typical vessel transit velocity in the channel under normal environmental conditions but not taken to be less than V_{MIN} (ft/s)
 V_{MIN} = minimum design impact velocity taken as not less than the yearly mean current velocity for the bridge location (ft/s)
 X = distance to face of pier from centerline of channel (ft)
 X_C = distance to edge of channel (ft)
 X_L = distance equal to 3.0 times the length overall of the design vessel (ft)

The length overall, LOA , for barge tows shall be taken as the total length of the tow plus the length of the tug/tow boat.

Figure 3.14.6-1—Design Collision Velocity Distribution

centerline of the vessel transit path in the channel was based on historical accident data. This data indicated that aberrant ships and barges that collide with bridge piers further away from the channel are moving at reduced velocities compared with those hitting piers located closer to the navigable channel limits. Aberrant vessels located at long distances from the channel are usually drifting with the current. Aberrant vessels, located very near the channel, are moving at velocities approaching that of ships and barges in the main navigation channel.

The exact distribution of the velocity reduction is unknown. However, a triangular distribution was chosen because of its simplicity as well as its reasonableness in modeling the aberrant vessel velocity situation. The use of the distance 3.0 times LOA in Figure 3.14.6-1 to define the limits at which the design velocity becomes equal to that of the water current was based on the observation that very few accidents, other than with drifting vessels, have historically occurred beyond that boundary.

The selection of the design collision velocity is one of the most significant design parameters associated with the vessel collision requirements. Judgment should be exercised in determining the appropriate design velocity for a vessel transiting the waterway. The chosen velocity should reflect the “typical” transit velocity of the design vessel under “typical” conditions of wind, current, visibility, opposing traffic, waterway geometry, etc. A different vessel velocity may be required for inbound vessels than for outbound vessels given the presence of currents that may exist in the waterway.

In waterways subject to seasonal flooding, consideration should be given to flood flow velocities in determining the minimum collision velocity.

In general, the design velocity should not be based on extreme values representing extreme events, such as exceptional flooding and other extreme environmental conditions. Vessels transiting under these conditions are not representative of the “annual average” situations reflecting the typical transit conditions.

3.14.7—Vessel Collision Energy

The kinetic energy of a moving vessel to be absorbed during a noneccentric collision with a bridge pier shall be taken as:

$$KE = \frac{C_H W V^2}{29.2} \quad (3.14.7-1)$$

where:

- KE = vessel collision energy (kip-ft)
 W = vessel displacement tonnage (tonne)
 C_H = hydrodynamic mass coefficient
 V = vessel impact velocity (ft/s)

C3.14.7

Eq. 3.14.7-1 is the standard $mV^2/2$ relationship for computing kinetic energy with conversion from mass to weight, conversion of units and incorporation of a hydrodynamic mass coefficient, C_H , to account for the influence of the surrounding water upon the moving vessel. Recommendations for estimating C_H for vessels moving in a forward direction were based on studies by Saul and Svensson (1980) and data published by PIANC (1984). It should be noted that these hydrodynamic mass coefficients are smaller than those normally used for ship berthing computations, in which a relatively large mass of water moves with the vessel as it approaches a dock from a lateral, or broadside, direction.

The vessel displacement tonnage, W , shall be based upon the loading condition of the vessel and shall include the empty weight of the vessel, plus consideration of the weight of cargo, DWT, for loaded vessels, or the weight of water ballast for vessels transiting in an empty or lightly loaded condition. The displacement tonnage for barge tows shall be the sum of the displacement of the tug/tow vessel and the combined displacement of a row of barges in the length of the tow.

The hydrodynamic mass coefficient, C_H , shall be taken as:

- If underkeel clearance exceeds $0.5 \times$ draft:

$$C_H = 1.05 \quad (3.14.7-2)$$

- If underkeel clearance is less than $0.1 \times$ draft:

$$C_H = 1.25 \quad (3.14.7-3)$$

Values of C_H may be interpolated from the range shown above for intermediate values of underkeel clearance. The underkeel clearance shall be taken as the distance between the bottom of the vessel and the bottom of the waterway.

3.14.8—Ship Collision Force on Pier

The head-on ship collision impact force on a pier shall be taken as:

$$P_s = 8.15 V \sqrt{DWT} \quad (3.14.8-1)$$

where:

P_s	=	equivalent static vessel impact force (kip)
DWT	=	deadweight tonnage of vessel (tonne)
V	=	vessel impact velocity (ft/s)

C3.14.8

The determination of the impact load on a bridge structure during a ship collision is complex and depends on many factors as follows:

- Structural type and shape of the ship's bow,
- Degree of water ballast carried in the forepeak of the bow,
- Size and velocity of the ship,
- Geometry of the collision, and
- Geometry and strength characteristics of the pier.

Eq. 3.14.8-1 was developed from research conducted by Woisin (1976) in West Germany to generate collision data with a view to protecting the reactors of nuclear-powered ships from collisions with other ships. The ship collision data resulted from collision tests with physical ship models at scales of 1:12.0 and 1:7.5. Woisin's results have been found to be in good agreement with the results of research conducted by other ship collision investigators worldwide (IABSE, 1983).

Figure C3.14.8-1 indicates the scatter in Woisin's test data due to the various collision factors discussed herein, the triangular probability density function used to model the scatter, and the selection of a 70 percent fractile force for use as an equivalent static impact force for bridge design. Using a 70 percent fractile force for a given design vessel, the number of smaller ships with a crushing strength greater than this force would be approximately equal to the number of larger ships with a crushing strength less than this force. Figure C3.14.8-2 indicates typical ship impact forces computed with Eq. 3.14.8-1.

Figure C3.14.8-1—Probability Density Function of Ship Impact Force Data

Figure C3.14.8-2—Typical Ship Impact Forces

3.14.9—Ship Bow Damage Length

The horizontal length of the ship's bow, crushed by impact with a rigid object, shall be taken as:

$$a_s = 1.54 \left(\frac{KE}{P_s} \right) \quad (3.14.9-1)$$

where:

a_s = bow damage length of ship (ft)
 KE = vessel collision energy (kip-ft)

C3.14.9

The average bow damage length, a , is computed based on the impact force averaged against the work path, $P(a)$, such that:

$$a = \frac{KE}{P(a)} \quad (C3.14.9-1)$$

The 1.54 coefficient used to compute the design ship damage depth in Eq. 3.14.9-1 results from the multiplication of the following factors:

P_S = ship impact force as specified in Eq. 3.14.8-1 (kip)

- 1.25 to account for the increase in average impact force over time versus damage length,
- 1.11 to account for the increase in average impact force to the 70 percent design fractile, and
- 1.11 to provide an increase in the damage length to provide a similar level of design safety as that used to compute P_S .

3.14.10—Ship Collision Force on Superstructure

3.14.10.1—Collision with Bow

The bow collision impact force on a superstructure shall be taken as:

$$P_{BH} = (R_{BH})(P_S) \quad (3.14.10.1-1)$$

where:

P_{BH} = ship bow impact force on an exposed superstructure (kip)

R_{BH} = ratio of exposed superstructure depth to the total bow depth

P_S = ship impact force specified in Eq. 3.14.8-1 (kip)

For the purpose of this Article, exposure is the vertical overlap between the vessel and the bridge superstructure with the depth of the impact zone.

3.14.10.2—Collision with Deck House

The deck house collision impact force on a superstructure shall be taken as:

$$P_{DH} = (R_{DH})(P_S) \quad (3.14.10.2-1)$$

where:

P_{DH} = ship deck house impact force (kip)

R_{DH} = reduction factor specified herein

P_S = ship impact force as specified in Eq. 3.14.8-1 (kip)

For ships exceeding 100,000 tonne, R_{DH} shall be taken as 0.10. For ships smaller than 100,000 tonne:

$$R_{DH} = 0.2 - \left(\frac{DWT}{100,000} \right) (0.10) \quad (3.14.10.2-2)$$

3.14.10.3—Collision with Mast

The mast collision impact force on a superstructure shall be taken as:

$$P_{MT} = 0.10P_{DH} \quad (3.14.10.3-1)$$

C3.14.10.1

Limited data exists on the collision forces between ship bows and bridge superstructure components.

C3.14.10.2

According to the Great Belt Bridge investigation in Denmark (Cowiconsult, Inc., 1981) forces for deck house collision with a bridge superstructure:

P_{DH} = 1,200 kip for the deck house collision of a 1,000 DWT freighter ship, and

P_{DH} = 6,000 kip for the deck house collision of a 100,000 DWT tanker ship.

Based on these values, the approximate empirical relationship of Eq. 3.14.10.2-1 was developed for selecting superstructure design impact values for deck house collision.

C3.14.10.3

Eq. 3.14.10.3-1 was developed by estimating the impact forces based on bridge girder and superstructure damage from a limited number of mast impact accidents.

where:

P_{MT} = ship mast impact force (kip)

P_{DH} = ship deck house impact force specified in Eq. 3.14.10.2-1 (kip)

3.14.11—Barge Collision Force on Pier

For the purpose of Article 3.14, the standard hopper barge shall be taken as an inland river barge with:

width	=	35.0 ft
length	=	195.0 ft
depth	=	12.0 ft
empty draft	=	1.7 ft
loaded draft	=	8.7 ft
DWT	=	1,700 tons

The collision impact force on a pier for a standard hopper barge shall be taken as:

- If $a_B < 0.34$ then:

$$P_B = 4,112a_B \quad (3.14.11-1)$$

- If $a_B \geq 0.34$ then:

$$P_B = 1,349 + 110a_B \quad (3.14.11-2)$$

where:

P_B = equivalent static barge impact force (kip)

a_B = barge bow damage length, specified in Eq. 3.14.12-1 (ft)

C3.14.11

There is less reported data on impact forces resulting from barge collisions than from ship collision. The barge collision impact forces determined by Eqs. 3.14.11-1 and 3.14.11-2 were developed from research conducted by Meir-Dornberg (1983) in West Germany. Meir-Dornberg's study included dynamic loading with a pendulum hammer on barge bottom models in scale 1:4.5, static loading on one bottom model in scale 1:6, and numerical analysis. The results for the standard European Barge, Type IIa, which has a similar bow to the standard hopper barge in the United States, are shown in Figure C3.14.11-1 for barge deformation and impact loading. No significant difference was found between the static and dynamic forces measured during the study. Typical barge tow impact forces using Eqs. 3.14.11-1 and 3.14.11-2 are shown in Figure C3.14.11-2.

where:

E_B = deformation energy (kip-ft)

$\bar{P}_B$ = average equivalent static barge impact force resulting from the study (kip)

Figure C3.14.11-1—Barge Impact Force, Deformation Energy, and Damage Length Data

Figure C3.14.11-2—Typical Hopper Barge Impact Forces

Since the barge collision load formulation is for a standard rake head log height of 2.0 to 3.0 feet, the possibility of deeper head logs that may occur in tanker barges and special deck barges should also be considered. In lieu of better information, the barge force may be increased in proportion to the head log height compared to that of the standard hopper barge.

3.14.12—Barge Bow Damage Length

The barge bow horizontal damage length for a standard hopper barge shall be taken as:

$$a_B = 10.2 \left(\sqrt{1 + \frac{KE}{5,672}} - 1 \right) \quad (3.14.12-1)$$

where:

a_B = barge bow damage length (ft)
 KE = vessel collision energy (kip-ft)

3.14.13—Damage at the Extreme Limit State

Inelastic behavior and redistribution of force effects is permitted in substructure and superstructure components, provided that sufficient ductility and redundancy of the remaining structure exists in the extreme event limit state to prevent catastrophic superstructure collapse.

As an alternative, pier protection may be provided for the bridge structure to eliminate or reduce the vessel collision loads applied to the bridge structure to acceptable levels.

C3.14.12

The relationship for barge horizontal damage length, a_B , was developed from the same research conducted on barge collisions by Meir-Dornberg, as discussed in Article C3.14.11.

C3.14.13

Two basic protection options are available to the Bridge Designer. The first option involves designing the bridge to withstand the impact loads in either an elastic or inelastic manner. If the response to collision is inelastic, the design must incorporate redundancy or other means to prevent collapse of the superstructure.

The second option is to provide a protective system of fenders, pile-supported structures, dolphins, islands, etc., either to reduce the magnitude of the impact loads to less than the strength of the bridge pier or superstructure components or to independently protect those components.

The requirements for either of these two options are general in nature because the actual design procedures that could be used vary considerably. This is particularly true for inelastic design. Because little information is available on the behavior of the inelastic deformation of materials and structures during the type of dynamic impacts associated with vessel impact, assumptions based on experience and sound engineering practice should be substituted.

3.14.14—Application of Impact Force

3.14.14.1—Substructure Design

For substructure design, equivalent static forces, parallel and normal to the centerline of the navigable channel, shall be applied separately as follows:

- 100 percent of the design impact force in a direction parallel to the alignment of the centerline of the navigable channel, or
- 50 percent of the design impact force in the direction normal to the direction of the centerline of the channel.

All components of the substructure, exposed to physical contact by any portion of the design vessel's hull or bow, shall be designed to resist the applied loads. The bow overhang, rake, or flair distance of ships and barges shall be considered in determining the portions of the substructure exposed to contact by the vessel. Crushing of the vessel's bow causing contact with any setback portion of the substructure shall also be considered.

The impact force in both design cases, specified herein, shall be applied to a substructure in accordance with the following criteria:

- For overall stability, the design impact force is applied as a concentrated force on the substructure at the mean high water level of the waterway, as shown in Figure 3.14.14.1-1, and
- For local collision forces, the design impact force is applied as a vertical line load equally distributed along the ship's bow depth, as shown in Figure 3.14.14.1-2. The ship's bow is considered to be raked forward in determining the potential contact area of the impact force on the substructure. For barge impact, the local collision force is taken as a vertical line load equally distributed on the depth of the head block, as shown in Figure 3.14.14.1-3.

C3.14.14.1

Two cases should be evaluated in designing the bridge substructure for vessel impact loadings:

- The overall stability of the substructure and foundation, assuming that the vessel impact acts as a concentrated force at the waterline, and
- The ability of each component of the substructure to withstand any local collision force resulting from a vessel impact.

The need to apply local collision forces on substructures exposed to contact by overhanging portions of a ship or barge's bow is well documented by accident case histories. The Sunshine Skyway Bridge in Tampa Bay, Florida, collapsed in 1980 as a result of the ship's bow impacting a pier column at a point 42.0 ft above the waterline. Ship and barge bow rake lengths are often large enough that they can even extend over protective fender systems and contact vulnerable bridge components, as shown in Figures C3.14.14.1-1 and C3.14.14.1-2. Bow shapes and dimensions vary widely, and the Designer may need to perform special studies to establish vessel bow geometry for a particular waterway location. Typical bow geometry data is provided in AASHTO (2009).

Figure 3.14.14.1-1—Ship Impact Concentrated Force on Pier

Figure 3.14.14.1-2—Ship Impact Line Load on Pier

Figure 3.14.14.1-3—Barge Impact Force on Pier

3.14.14.2—Superstructure Design

For superstructure design, the design impact force shall be applied as an equivalent static force transverse to the superstructure component in a direction parallel to the alignment of the centerline of the navigable channel.

3.14.15—Protection of Substructures

Protection may be provided to reduce or to eliminate the exposure of bridge substructures to vessel collision by physical protection systems, including fenders, pile cluster, pile-supported structures, dolphins, islands, and combinations thereof.

Severe damage and/or collapse of the protection system may be permitted, provided that the protection system stops the vessel prior to contact with the pier or redirects the vessel away from the pier.

Figure C3.14.14.1-1—Plan of Ship Bow Overhang Impacting Pier

Figure C3.14.14.1-2—Elevation of Barge Bow Impacting Pier

C3.14.14.2

The ability of various portions of a ship or barge to impact a superstructure component depends on the available vertical clearance under the structure, the water depth, vessel type and characteristics, and the loading condition of the vessel.

C3.14.15

The development of bridge protection alternatives for vessel collisions generally follows three approaches:

- Reducing the annual frequency of collision events, for example, by improving navigation aids near a bridge;
- Reducing the probability of collapse, for example, by imposing vessel speed restrictions in the waterway; or
- Reducing the disruption costs of a collision, for example, by physical protection and motorist warning systems.

Because modifications to navigation aids in the waterway and vessel operating conditions are normally beyond the Bridge Designer's ability to implement, the primary area of bridge protection to be considered by the Designer are physical protection and motorist warning systems.

The current practice in the design of protective structures is almost invariably based on energy considerations. It is assumed that the loss of kinetic energy of the vessel is transformed into an equal amount of energy absorbed by the protective structure. The kinetic impact energy is dissipated by the work done by flexure, shear, torsion, and displacement of the components of the protective system.

Design of a protective system is usually an iterative process in which a trial configuration of a protective system is initially developed. For the trial, a force versus deflection diagram is developed via analysis or physical modeling and testing. The area under the diagram is the energy capacity of the protective system. The forces and energy capacity of the protective system is then compared with the design vessel impact force and energy to see if the vessel loads have been safely resisted.

3.14.16—Security Considerations

The Owner of the bridge shall establish the size and velocity of the vessel to be used in bridge security analysis.

The vessel impact force shall be determined in accordance with Articles 3.14.8, 3.14.10.1, 3.14.10.2, or 3.14.10.3, as applicable.

The probability of bridge collapse due to intentional collision with the design vessel at the design speed shall be taken equal to PC , which shall be determined using the provisions of Article 3.14.5.4. The design vessel and velocity are site-specific variables that should be selected by the Owner as part of a security assessment.

C3.14.16

As the intent of intentionally ramming a vessel into a bridge is to cause the bridge to collapse, the velocity of the vessel at the moment of collision is expected to be higher than the normal travel speed. In addition to accounting for the effects of impact, consideration should also be given to the potential for vessel-delivered explosives and subsequent fire. The physical limitations on the velocity and size of the vessel should be taken into account when determining the design velocity for intentional collision as well as the likely maximum explosive size that can be delivered. For example, the velocity of a barge tow is limited by the power of the tug boats and by the geometry of the waterway in the approach to the bridge. Similarly, the factors limiting the size of the vessel should be considered when determining the design vessel.

In case of accidental collision, determining the annual probability of collapse using Eq. 3.14.5-1 involves the annual number of vessels, N , the probability of vessel aberrancy, PA , and the geometric probability of a collision, PG . In the case of intentional collision, the value of each of the three variables may be taken as 1.0. Therefore, the probability of collapse in case of intentional collision is taken equal to PC .

3.15—BLAST LOADING: BL

Where it has been determined that a bridge or a bridge component should be designed for intentional or unintentional blast force, the following should be considered:

- Size of explosive charge,
- Shape of explosive charge,
- Type of explosive,
- Stand-off distance,
- Location of the charge,
- Possible modes of delivery and associated capacities (e.g., maximum charge weight will depend upon vehicle type and can include cars, trucks, ships, etc.), and
- Fragmentation associated with vehicle-delivered explosives.

C3.15

The size, shape, location, and type of an explosive charge determine the intensity of the blast force produced by an explosion. For comparison purposes, all explosive charges are typically converted to their equivalent TNT charge weights.

Stand-off refers to the distance between the center of an explosive charge and a target. Due to the dispersion of blast waves in the atmosphere, increasing stand-off causes the peak pressure on a target to drop as a cubic function of the distance (i.e., for a given quantity of explosives, doubling the stand-off distance causes the peak pressure to drop by a factor of eight). The location of the charge determines the amplifying effects of the blast wave reflecting from the ground surface or from the surfaces of surrounding structural elements. The location of the charge also determines the severity of damage caused by fragments from the components closest to the blast traveling away from the blast center.

Information on the analysis of blast loads and their effects on structures may be found in J. M. Biggs (1964), W. E. Baker, et al. (1983), Department of the Army (1986, 1990), and Bulson (1997).

APPENDIX A3—SEISMIC DESIGN FLOWCHARTS

Figure A3-1—Seismic Design Procedure Flow Chart

Figure A3-2—Seismic Detailing and Foundation Design Flow Chart

APPENDIX B3—OVERSTRENGTH RESISTANCE

Article 3.10.9.4.3a defines the forces resulting from plastic hinging, i.e., a column reaching its ultimate moment capacity, in the columns and presents two procedures. One is for a single column hinging about its two principal axes; this is also applicable for piers and bents acting as single columns. The other procedure is for a multiple column bent in the plane of the bent. The forces are based on the potential overstrength resistance of the materials, and to be valid the design detail requirements of this Section must be used so that plastic hinging of the columns can occur. The overstrength resistance results from actual properties being greater than the minimum specified values and is implemented by specifying resistance factors greater than unity. This fact must be accounted for when forces generated by yielding of the column are used as design forces. Generally, overstrength resistance depends on the following factors:

- The actual size of the column and the actual amount of reinforcing steel.
 - The effect of an increased steel strength over the specified f_y and for strain hardening effects.
 - The effect of an increased concrete strength over the specified f'_c and confinement provided by the transverse steel.
- Also, with time, concrete will gradually increase in strength.
- The effect of an actual concrete ultimate compressive strain above 0.003.

Column Size and Reinforcement Configuration

The Design Engineer should select the minimum column section size and steel reinforcement ratio when satisfying structural design requirements. As these parameters increase, the overstrength resistance increases. This may lead to an increase in the foundation size and cost. A size and reinforcement ratio which forces the design below the nose of the interaction curve is preferable, especially in high seismic areas. However, the selection of size and reinforcement must also satisfy architectural, and perhaps other requirements, which may govern the design.

Increase in Reinforcement Strength

Almost all reinforcing bars will have a yield strength larger than the minimum specified value which may be up to 30 percent higher, with an average increase of 12 percent. Combining this increase with the effect of strain hardening, it is realistic to assume an increased yield strength of $1.25 f_y$ when computing the column overstrength.

Increase in Concrete Strength

Concrete strength is defined as the specified 28-day compression strength; this is a low estimate of the strength expected in the field. Typically, conservative concrete batch designs result in actual 28-day strengths of about 20–25 percent higher than specified. Concrete will also continue to gain strength with age. Tests on cores taken from older California bridges built in the 1950s and 1960s have consistently yielded compression strength in excess of $1.5 f'_c$. Concrete compression strength is further enhanced by the possible confinement provided by the transverse reinforcement. Rapid loading due to seismic forces could also result in significant increase in strength, i.e., strain rate effect. In view of all the above, the actual concrete strength when a seismic event occurs is likely to significantly exceed the specified 28-day strength. Therefore, an increased concrete strength of $1.5 f'_c$ could be assumed in the calculation of the column overstrength resistance.

Ultimate Compressive Strain, ϵ_c

Although tests on unconfined concrete show 0.003 to be a reasonable strain at first crushing, tests on confined column sections show a marked increase in this value. The use of such a low extreme fiber strain is a very conservative estimate of strains at which crushing and spalling first develop in most columns, and considerably less than the expected strain at maximum response to the design seismic event. Research has supported strains on the order of 0.01 and higher as the likely magnitude of ultimate compressive strain. Therefore, designers could assume a value of ultimate strain equal to 0.01 as a realistic value.

For calculation purposes, the thickness of clear concrete cover used to compute the section overstrength shall not be taken to be greater than 2.0 in. This reduced section shall be adequate for all applied loads associated with the plastic hinge.

Overstrength Capacity

The derivation of the column overstrength capacity is depicted in Figure B3-1. The effect of higher material properties than specified is illustrated by comparing the actual overstrength curve, computed with realistic f'_c , f_y , and ϵ_c values, to the

nominal strength interaction curve, P_n , M_n . It is generally satisfactory to approximate the overstrength capacity curve by multiplying the nominal moment strength by the 1.3 factor for axial loads below the nose of the interaction curve, i.e., P_n , $1.3 M_n$ curve. However, as shown, this curve may be in considerable error for axial loads above the nose of the interaction curve. Therefore, it is recommended that the approximate overstrength curve be obtained by multiplying both P_n and M_n by $\phi = 1.3$, i.e., $1.3 P_n$, $1.3 M_n$. This curve follows the general shape of the actual curve very closely at all levels of axial loads.

In the light of the above discussion, it is recommended that:

- For all bridges with axial loads below P_b , the overstrength moment capacity shall be assumed to be 1.3 times the nominal moment capacity.
- For bridges in Zones 3 and 4 with operational classification of “Ordinary,” and for all bridges in Zone 2 for which plastic hinging has been invoked, the overstrength curve for axial loads greater than P_b shall be approximated by multiplying both P_n and M_n by $\phi = 1.3$.
- For bridges in Zones 3 and 4 with operational classification of “Recovery” or “Critical,” the overstrength curve for axial loads greater than P_b shall be computed using realistic values for f'_c , f_y and ϵ_c as recommended in Table B3-1 or from values based on actual test results. The column overstrength, thus calculated, should not be less than the value estimated by the approximate curve based on $1.3 P_n$, $1.3 M_n$.

Table B3-1—Recommended Increased Values of Materials Properties

Increased f_y (minimum)	$1.25 f_y$
Increased f'_c	$1.5 f'_c$
Increased ϵ_c	0.01

Shear Failure

The shear mode of failure in a column or pile bent will probably result in a partial or total collapse of the bridge; therefore, the design shear force must be calculated conservatively. In calculating the column or pile bent shear force, consideration must be given to the potential locations of plastic hinges. For flared columns, these may occur at the top and bottom of the flare. For multiple column bents with a partial-height wall, the plastic hinges will probably occur at the top of the wall unless the wall is structurally separated from the column. For columns with deeply embedded foundations, the plastic hinge may occur above the foundation mat or pile cap. For pile bents, the plastic hinge may occur above the calculated point of fixity. Because of the consequences of a shear failure, it is recommended that conservatism be used in locating possible plastic hinges such that the smallest potential column length be used with the plastic moments to calculate the largest potential shear force for design.

Figure B3-1—Development of Approximate Overstrength Interaction Curves from Nominal Strength Curves after Gajer and Wagh (1994)

SECTION 4

STRUCTURAL ANALYSIS AND EVALUATION

Commentary is opposite the text it annotates.

4.1—SCOPE

This Section describes methods of analysis suitable for the design and evaluation of bridges, and is limited to the modeling of structures and the determination of force effects.

Other methods of analysis that are based on documented material characteristics and that satisfy equilibrium and compatibility may also be used.

In general, bridge structures are to be analyzed elastically. However, this Section permits the inelastic analysis or redistribution of force effects in some continuous beam superstructures. It specifies inelastic analysis for compressive members behaving inelastically and as an alternative for extreme event limit states.

C4.1

This Section identifies and promotes the application of methods of structural analysis that are suitable for bridges. The selected method of analysis may vary from the approximate to the very sophisticated, depending on the size, complexity, and priority of the structure. The primary objective in the use of more sophisticated methods of analysis is to obtain a better understanding of structural behavior. Such improved understanding may often, but not always, lead to the potential for saving material.

The methods of analysis outlined herein, which are suitable for the determination of deformations and force effects in bridge structures, have been successfully demonstrated, and most have been used for years. Although many methods will require a computer for practical implementation, simpler methods that are amenable to hand calculation and/or the use of existing computer programs based on line-structure analysis are also provided. Comparison with hand calculations should always be encouraged and basic equilibrium checks should be standard practice.

With rapidly improving computing technology, the more refined and complex methods of analysis are expected to become commonplace. Hence, this Section addresses the assumptions and limitations of such methods. It is important that the user understand the method employed and its associated limitations.

In general, the suggested methods of analysis are based on linear material models. This does not mean that cross-sectional resistance is limited to the linear range. This presents an obvious inconsistency in that the analysis is based on material linearity and the resistance model may be based on inelastic behavior for the strength limit states. This same inconsistency existed, however, in the load factor design method of the *AASHTO Standard Specifications for Highway Bridges*, and is present in design codes of other nations using a factored design approach.

The loads and load factors, defined in Section 3, and the resistance factors specified throughout these Specifications were developed using probabilistic principles combined with analyses based on linear material models. Hence, analysis methods based on material nonlinearities to obtain force effects that are more realistic at the strength limit states and subsequent economics that may be derived are permitted only where explicitly outlined herein.

Some nonlinear behavioral effects are addressed in both the analysis and resistance sections. For example, long column behavior may be modeled via geometric nonlinear methods and may also be modeled using approximate formulas in Sections 5, 6, 7, and 8. Either method may be used, but the more refined formulations are recommended.

4.2—DEFINITIONS

Accepted Method of Analysis—A method of analysis that requires no further verification and that has become a regular part of structural engineering practice.

Arc Span—Distance between centers of adjacent bearings or other points of support, measured horizontally along the centerline of a horizontally curved member.

Aspect Ratio—Ratio of the length to the width of a rectangle.

Boundary Conditions—Structural restraint characteristics regarding the support for and/or the continuity between structural models.

Bounding—Taking two or more extreme values of parameters to envelop the response with a view to obtaining a conservative design.

Central Angle—The angle included between two points along the centerline of a curved bridge measured from the center of the curve, as shown in Figure 4.6.1.2.3-1.

Classical Deformation Method—A method of analysis in which the structure is subdivided into components whose stiffness can be independently calculated. Equilibrium and compatibility among the components is restored by determining the deformations at the interfaces.

Classical Force Method—A method of analysis in which the structure is subdivided into statically determinate components. Compatibility among the components is restored by determining the interface forces.

Closed-Box Section—A cross-section composed of two vertical or inclined webs which has at least one completely enclosed cell. A closed-section member is effective in resisting applied torsion by developing shear flow in the webs and flanges.

Closed-Form Solution—One or more equations, including those based on convergent series, that permit calculation of force effects by the direct introduction of loads and structural parameters.

Compatibility—The geometrical equality of movement at the interface of joined components.

Component—A structural unit requiring separate design consideration; synonymous with *Member*.

Condensation—Relating the variables to be eliminated from the analysis to those being kept to reduce the number of equations to be solved.

Core Width—The width of the superstructure of monolithic construction minus the deck overhangs.

Cross-Section Distortion—Change in shape of the cross-section profile due to torsional loading.

Curved Girder—An I-, closed-box, or tub girder that is curved in a horizontal plane.

Damper—A device that transfers and reduces forces between superstructure elements and/or superstructure and substructure elements, while permitting thermal movements. The device provides damping by dissipating energy under seismic, braking, or other dynamic loads.

Deck—A component, with or without wearing surface, directly supporting wheel loads.

Deck System—A superstructure in which the deck is integral with its supporting components or in which the effects or deformation of supporting components on the behavior of the deck is significant.

Deformation—A change in structural geometry due to force effects, including axial displacement, shear displacement, rotations, or a combination thereof.

Degree-of-Freedom—One of a number of translations or rotations required to define the movement of a node. The displaced shape of components and/or the entire structure may be defined by a number of degrees-of-freedom.

Design—Proportioning and detailing the components and connections of a bridge to satisfy the requirements of these Specifications.

Dynamic Degree-of-Freedom—A degree-of-freedom with which mass or mass effects have been associated.

Elastic—A structural material behavior in which the ratio of stress to strain is constant; the material returns to its original unloaded state upon load removal.

Element—A part of a component or member consisting of one material.

End Zone—Region of structures where normal beam theory does not apply due to structural discontinuity and/or distribution of concentrated loads.

Equilibrium—A state where the sum of forces and moments about any point in space is 0.0.

Equivalent Beam—A single straight or curved beam resisting both flexural and torsional effects.

Equivalent Strip—An artificial linear element, isolated from a deck for the purpose of analysis, in which extreme force effects calculated for a line of wheel loads, transverse or longitudinal, will approximate those actually taking place in the deck.

Finite Difference Method—A method of analysis in which the governing differential equation is satisfied at discrete points on the structure.

Finite Element Method—A method of analysis in which a structure is discretized into elements connected at nodes, the shape of the element displacement field is assumed, partial or complete compatibility is maintained among the element interfaces, and nodal displacements are determined by using energy variational principles or equilibrium methods.

Finite Strip Method—A method of analysis in which the structure is discretized into parallel strips. The shape of the strip displacement field is assumed and partial compatibility is maintained among the element interfaces. Model displacement parameters are determined by using energy variational principles or equilibrium methods.

First-Order Analysis—Analysis in which equilibrium conditions are formulated on the undeformed structure; that is, the effect of deflections is not considered in writing equations of equilibrium.

Flange Lateral Bending—Bending of a flange about an axis perpendicular to the flange plane due to lateral loads applied to the flange and/or nonuniform torsion in the member.

Flange Lateral Bending Stress—The normal stress caused by flange lateral bending.

Folded Plate Method—A method of analysis in which the structure is subdivided into plate components, and both equilibrium and compatibility requirements are satisfied at the component interfaces.

Footprint—The contact area between wheel and roadway surface.

Force Effect—A deformation, stress, or stress resultant, i.e., axial force, shear force, or flexural or torsional moment, caused by applied loads, imposed deformations, or volumetric changes.

Foundation—A supporting element that derives its resistance by transferring its load to the soil or rock supporting the bridge.

Frame Action—Transverse continuity between the deck and the webs of cellular cross-section or between the deck and primary components in large bridges.

Frame Action for Wind—Transverse flexure of the beam web and that of framed stiffeners, if present, by which lateral wind load is partially or completely transmitted to the deck.

Girder Radius—The radius of the circumferential centerline of a segment of a curved girder.

Global Analysis—Analysis of a structure as a whole.

Governing Position—The location and orientation of transient load to cause extreme force effects.

Grid Method—A grid method of analysis of girder bridges in which the longitudinal girders are modeled individually using beam elements and the cross-frames are typically modeled as equivalent beam elements. For composite girders, a tributary deck width is considered in the calculation of individual girder cross-section properties.

Inelastic—Any structural behavior in which the ratio of stress and strain is not constant, and part of the deformation remains after load removal.

Lane Live Load—The combination of tandem axle and uniformly distributed loads or the combination of the design truck and design uniformly distributed load.

Large Deflection Theory—Any method of analysis in which the effects of deformation upon force effects is taken into account.

Lever Rule—The statical summation of moments about one point to calculate the reaction at a second point.

Linear Response—Structural behavior in which deflections are directly proportional to loads.

Local Analysis—An in-depth study of strains and stresses in or among components using force effects obtained from a more global analysis.

Local Structural Stress—The stress at a welded detail including all stress-raising effects of a structural detail but excluding all stress concentrations due to the local weld profile itself.

Member—Same as *Component*.

Method of Analysis—A mathematical process by which structural deformations, forces, and stresses are determined.

Model—A mathematical or physical idealization of a structure or component used for analysis.

Monolithic Construction—Single-cell steel and/or concrete box bridges, solid or cellular cast-in-place concrete deck systems, and decks consisting of precast, solid, or cellular longitudinal elements effectively tied together by transverse post-tensioning.

M/R Method—An approximate method for the analysis of curved box girders in which the curved girder is treated as an equivalent straight girder to calculate flexural effects and as a corresponding straight conjugate beam to calculate the concomitant St. Venant torsional moments due to curvature.

Multibeam Decks—Bridges with superstructure members consisting of adjacent precast sections with the top flange as a complete full-depth integral deck or a structural deck section placed as an overlay. Sections can be closed cell boxes or open stemmed.

Negative Moment—Moment producing tension at the top of a flexural element.

Node—A point where finite elements or grid components meet; in conjunction with finite differences, a point where the governing differential equations are satisfied.

Nonlinear Response—Structural behavior in which the deflections are not directly proportional to the loads due to stresses in the inelastic range, or deflections causing significant changes in force effects, or a combination thereof.

Nonuniform Torsion—An internal resisting torsion in thin-walled sections, also known as warping torsion, producing shear stress and normal stresses, and under which cross-sections do not remain plane. Members resist the externally applied torsion by warping torsion and St. Venant torsion. Each of these components of internal resisting torsion varies along the member length, although the externally applied concentrated torque may be uniform along the member between two adjacent points of torsional restraint. Warping torsion is dominant over St. Venant torsion in members having open cross-sections, whereas St. Venant torsion is dominant over warping torsion in members having closed cross-sections.

Open Section—A cross-section which has no enclosed cell. An open-section member resists torsion primarily by nonuniform torsion, which causes normal stresses at the flange tips.

Orthotropic—Perpendicular to each other, having physical properties that differ in two or more orthogonal directions.

Panel Point—The point where centerlines of members meet, usually in trusses, arches, or cable-stayed and suspension bridges.

Pin Connection—A connection among members by a notionally frictionless pin at a point.

Pinned End—A boundary condition permitting free rotation but not translation in the plane of action.

Plate and Eccentric Beam Method—A method of analysis of composite girder bridges in which the bridge deck is modeled using shell finite elements, the longitudinal girders are modeled using beam elements, and the cross-frames are typically modeled as equivalent beam elements. The girder and cross-frame elements are offset from the deck elements to account for the structural depth of these components relative to the deck.

Point of Contraflexure—The point where the sense of the flexural moment changes; synonymous with point of inflection.

Positive Moment—Moment producing tension at the bottom of a flexural element.

Primary Member—A member designed to carry the loads applied to the structure as determined from an analysis.

Rating Vehicle—A sequence of axles used as a common basis for expressing bridge resistance.

Refined Methods of Analysis—Methods of structural analysis that consider the entire superstructure as an integral unit and provide the required deflections and actions.

Restrainers—A system of high-strength cables or rods that transfers forces between superstructure elements and/or superstructure and substructure elements under seismic or other dynamic loads after an initial slack is taken up, while permitting thermal movements.

Rigidity—Force effect caused by a corresponding unit deformation per unit length of a component.

Secondary Member—A member in which stress is not normally evaluated in the analysis.

Second-Order Analysis—Analysis in which equilibrium conditions are formulated on the deformed structure; that is, in which the deflected position of the structure is used in writing the equations of equilibrium.

Series or Harmonic Method—A method of analysis in which the load model is subdivided into suitable parts, allowing each part to correspond to one term of a convergent infinite series by which structural deformations are described.

Shear Flow—Shear force per unit width acting parallel to the edge of a plate element.

Shear Lag—Nonlinear distribution of normal stress across a component due to shear distortions.

Shock Transmission Unit (STU)—A device that provides a temporary rigid link between superstructure elements and/or superstructure and substructure elements under seismic, braking, or other dynamic loads, while permitting thermal movements.

Skew Angle—Angle between the centerline of a support and a line normal to the roadway centerline.

Small-Deflection Theory—A basis for methods of analysis where the effects of deformation upon force effects in the structure is neglected.

Spacing of Beams—The center-to-center distance between lines of support.

Spine Beam Model—An analytical model of a bridge in which the superstructure is represented by a single beam element or a series of straight, chorded beam elements located along the centerline of the bridge.

Spread Beams—Beams not in physical contact with one another, carrying a cast-in-place concrete deck.

Stiffness—Force effect resulting from a unit deformation.

Strain—Elongation per unit length.

Stress Range—The algebraic difference between extreme stresses.

St. Venant Torsion—That portion of the internal resisting torsion in a member producing only pure shear stresses on a cross-section; also referred to as pure torsion or uniform torsion.

Submodel—A constituent part of the global structural model.

Superimposed Deformation—Effect of settlement, creep, and change in temperature and/or moisture content.

Superposition—The situation where the force effect due to one loading can be added to the force effect due to another loading. Use of superposition is only valid when the stress-strain relationship is linearly elastic and the small-deflection theory is used.

Tandem—Two closely spaced and mechanically interconnected axles of equal weight.

Through-Thickness Stress—Bending stress in a web or box flange induced by distortion of the cross-section.

Torsional Shear Stress—Shear stress induced by St. Venant torsion.

Tub Section—An open-topped section which is composed of a bottom flange, two inclined or vertical webs, and top flanges.

Uncracked Section—A section in which the concrete is assumed to be fully effective in tension and compression.

V-Load Method—An approximate method for the analysis of curved I-girder bridges in which the curved girders are represented by equivalent straight girders and the effects of curvature are represented by vertical and lateral forces applied at cross-frame locations. Lateral flange bending at brace points due to curvature is estimated.

Warping Stress—Normal stress induced in the cross-section by warping torsion and/or by distortion of the cross-section.

Wheel Load—One-half of a specified design axle load.

Yield Line—A plastic hinge line.

Yield Line Method—A method of analysis in which a number of possible yield line patterns are examined in order to determine load-carrying capacity.

4.3—NOTATION

A	=	area of a stringer, beam, or girder (in. ²) (4.6.2.2.1) (C4.6.2.2.1)
A_b	=	cross-sectional area of barrier (in. ²) (4.6.2.6.1)
A_c	=	cross-section area—transformed for steel beams (in. ²) (C4.6.6)
A_o	=	area enclosed by centerlines of elements (in. ²) (C4.6.2.2.1)
a	=	portion of span subject to a transition in effective flange width taken as the lesser of the physical flange width on each side of the web shown in Figure 4.6.2.6.2-3 or one-quarter of the span length (in.) (4.6.2.6.2)
B	=	spacing between orthotropic girder web plates or transverse beams (in.) (4.6.2.6.4)
b	=	width of a beam (in.); width of plate element (in.); physical flange width each side of the web (in.) (4.6.2.2.1) (C4.6.2.2.1) (4.6.2.6.2)
b_e	=	effective flange width corresponding to the particular position of the section of interest in the span as specified in Figure 4.6.2.6.2-1 (in.) (4.6.2.6.2)
b_m	=	effective flange width for interior portions of a span as determined from Figure 4.6.2.6.2-2; a special case of b_e (in.) (4.6.2.6.2)
b_n	=	effective flange width for normal forces acting at anchorage zones (in.) (4.6.2.6.2)
b_o	=	width of web projected to midplane of deck as shown in Figure 4.6.2.6.2-3c (in.) (4.6.2.6.2)
b_{od}	=	effective width of orthotropic deck (in.) (4.6.2.6.4)
b_s	=	effective flange width at interior support or for cantilever arm as determined from Figure 4.6.2.6.2-2; a special case of b_e (in.) (4.6.2.6.2) (C4.6.2.6.2)
C	=	continuity factor; stiffness parameter (4.6.2.1.8) (4.6.2.2.1)
C_m	=	moment gradient coefficient (4.5.3.2.2b)
C_w	=	girder warping torsional constant (in. ⁶) (C4.6.3.3.2)
c_1	=	parameter for skewed supports (4.6.2.2.2e)
D	=	web depth (ft); D_x/D_y ; width of distribution per lane (ft) (C4.6.1.2.4b) (4.6.2.1.8) (4.6.2.2.1)
D_x	=	flexural rigidity of the deck in main bar direction (kip-in. ² /in.) (4.6.2.1.8)
D_y	=	flexural rigidity of the deck perpendicular to main bar direction (kip-in. ² /in.) (4.6.2.1.8)
d	=	depth of a beam or stringer (in.); depth of the member (ft) (4.6.2.2.1) (C4.6.2.7.1)
d_e	=	horizontal distance from the centerline of the exterior web of exterior beam at the deck level to the interior edge of curb or traffic barrier (ft) (4.6.2.2.1)
d_o	=	depth of superstructure (in.) (4.6.2.6.2)
E	=	modulus of elasticity (ksi); equivalent width (in.); equivalent distribution width perpendicular to span (in.) (4.5.3.2.2b) (4.6.2.3) (4.6.2.10.2) (C4.6.6)
E_B	=	modulus of elasticity of beam material (ksi) (4.6.2.2.1)
E_c	=	modulus of elasticity of column (ksi) (C4.6.2.5)
E_D	=	modulus of elasticity of deck material (ksi) (4.6.2.2.1)
E_g	=	modulus of elasticity of beam or other restraining member (ksi) (C4.6.2.5)
E_{MOD}	=	cable modulus of elasticity, modified for nonlinear effects (ksi) (4.6.3.7)
E_{span}	=	equivalent distribution length parallel to span (in.) (4.6.2.10.2)
e	=	correction factor for distribution; eccentricity of a design truck or design lane load from the center of gravity of the pattern of girders (ft) (4.6.2.2.1) (C4.6.2.2.2d)
e_g	=	distance between the centers of gravity of the beam and deck (in.) (4.6.2.2.1)
f_c	=	factored stress, corrected to account for second-order effects (ksi) (4.5.3.2.2b)
f_{2b}	=	stress corresponding to M_{2b} (ksi) (4.5.3.2.2b)
f_{2s}	=	stress corresponding to M_{2s} (ksi) (4.5.3.2.2b)
G	=	final force effect applied to a girder (kip or kip-ft); shear modulus (ksi) (4.6.2.2.5) (C4.6.3.3.1)
G_a	=	ratio of stiffness of column to stiffness of members resisting column bending at “a” end (C4.6.2.5)
G_b	=	ratio of stiffness of column to stiffness of members resisting column bending at “b” end (C4.6.2.5)
G_D	=	force effect due to design loads (kip or kip-ft) (4.6.2.2.5)
G_p	=	force effect due to overload truck (kip or kip-ft) (4.6.2.2.5)
g	=	live load distribution factor representing the number of design lanes; acceleration of gravity (ft/s ²) (4.6.2.2.1) (C4.7.4.3.2)
g_m	=	multiple-lane live load distribution factor (4.6.2.2.5)
g_1	=	single-lane live load distribution factor (4.6.2.2.5)
H	=	depth of fill from top of culvert to top of pavement (in.); centroidal distance between the bottom strut member of a cross-frame and the concrete deck (in.); average height of substructure supporting the seat under consideration (ft) (4.6.2.10.2) (C4.6.3.3.4a) (4.7.4.4)
H, H_1, H_2	=	horizontal component of cable force (kip) (4.6.3.7)

h	=	depth of deck (in.) (4.6.2.1.3)
I	=	moment of inertia about axis under consideration (in. ⁴) (4.5.3.2.2b)
I_C	=	I-girder bridge connectivity index, taken equal to the maximum of the values of Eq. 4.6.3.3.2-1 determined for each span of the bridge (4.6.3.3.2)
I_c	=	moment of inertia of column (in. ⁴); inertia of cross-section—transformed for steel beams (in. ⁴) (C4.6.2.5) (C4.6.6)
I_g	=	moment of inertia of member acting to restrain column bending (in. ⁴) (C4.6.2.5)
IM	=	dynamic load allowance (C4.7.2.1)
I_p	=	polar moment of inertia (in. ⁴) (4.6.2.2.1) (C4.6.2.2.1)
I_S	=	bridge skew index, taken equal to the maximum of the values of Eq. 4.6.3.3.2-2 determined for each span of the bridge (4.6.3.3.2)
I_s	=	moment of inertia of equivalent strip (in. ⁴) (4.6.2.1.5)
I_x, I_y	=	moments of inertia per unit width of deck (4.6.2.1.8)
J	=	St. Venant torsional inertia (in. ⁴) (C4.6.2.2.1)
K	=	effective length factor for columns and arch ribs; constant for different types of construction; effective length factor for columns in the plane of bending (4.5.3.2.2b) (4.5.3.2.2c) (4.6.2.2.1) (4.6.2.5)
K_g	=	longitudinal stiffness parameter (in. ⁴) (4.6.2.2.1)
k	=	factor used in calculation of distribution factor for multibeam bridges (4.6.2.2.1)
k_s	=	strip stiffness (kip/in.) (4.6.2.1.5)
L	=	span length of deck (ft); span length (ft); span length of beam (ft); length of bridge deck (ft) (4.6.2.1.3) (4.6.2.1.8) (4.6.2.2.1) (4.6.2.6.4) (C4.6.2.7.1) (C4.7.4.3.2c) (4.7.4.4)
L_{as}	=	effective arc span of a horizontally curved girder (ft) (4.6.1.2.4b)
L_b	=	spacing of brace points, cross-frames, or diaphragms (ft) (C4.6.2.7.1)
L_c	=	unbraced length of column (in.) (C4.6.2.5)
L_g	=	unsupported length of beam or other restraining member (in.) (C4.6.2.5)
L_s	=	span length at the centerline (ft) (4.6.3.3.2)
$LLDF$	=	factor for distribution of live load with depth of fill, 1.15 or 1.00, as specified in Article 3.6.1.2.6 (4.6.2.10.2)
L_T	=	length of tire contact area parallel to span, as specified in Article 3.6.1.2.5 (in.) (4.6.2.10.2)
L_1	=	modified span length taken to be equal to the lesser of the actual span or 60.0 (ft); modified span length taken equal to the lesser of the actual span or 60.0 (ft) (4.6.2.3)
ℓ	=	unbraced length of a horizontally curved girder (ft) (C4.6.1.2.4b)
ℓ_i	=	a notional span length (ft) (4.6.2.6.2)
ℓ_u	=	unsupported length of a compression member (in.); one-half of the length of the arch rib (ft) (4.5.3.2.2b) (4.5.3.2.2c)
M	=	major-axis bending moment in a horizontally curved girder (kip-ft) (C4.6.1.2.4b)
$M_{parallel}$	=	moment due to live load in filled or partially filled grid deck when main bars are parallel to traffic (kip-in/in.) (4.6.2.1.8)
$M_{transverse}$	=	moment due to live load in filled or partially filled grid deck when main bars are perpendicular to traffic (kip-in/in.) (4.6.2.1.8)
M_c	=	factored moment, corrected to account for second-order effects (kip-ft); moment required to restrain uplift caused by thermal effects (kip-in.) (4.5.3.2.2b) (C4.6.6)
M_{lat}	=	flange lateral bending moment (kip-ft) (C4.6.1.2.4b)
MM	=	multimode elastic method (4.7.4.3.1)
M_n	=	nominal flexural strength (4.7.4.5)
M_w	=	maximum lateral moment in the flange due to the factored wind loading (kip-ft) (C4.6.2.7.1)
M_{1b}	=	smaller end moment on compression member due to factored gravity loads that result in no appreciable sidesway; positive if member is bent in single curvature, negative if bent in double curvature (kip-ft) (4.5.3.2.2b)
M_{2b}	=	moment on compression member due to factored gravity loads that result in no appreciable sidesway calculated by conventional first-order elastic frame analysis; always positive (kip-ft) (4.5.3.2.2b)
M_{2s}	=	moment on compression member due to factored lateral or gravity loads that result in sidesway, Δ , greater than $\ell_u/1,500$, calculated by conventional first-order elastic frame analysis; always positive (kip-ft) (4.5.3.2.2b)
m	=	bridge type constant, equal to 1 for simple-span bridges or bridge units, and equal to 2 for continuous-span bridges or bridge units, determined at the construction stage being evaluated (4.6.3.3.2)
N	=	constant for determining the lateral flange bending moment in I-girder flanges due to curvature, taken as 10 or 12 in past practice; axial force (kip); minimum support length (in.) (C4.6.1.2.4b) (C4.6.6) (4.7.4.4)
N_b	=	number of beams, stringers, or girders (4.6.2.2.1) (C4.6.2.2.2c) (C4.6.2.2.2d)
N_c	=	number of cells in a concrete box girder (4.6.2.2.1) (4.6.2.2.2b)

N_L	= number of design lanes (4.6.2.2.1) (C4.6.2.2.1) (C4.6.2.2.2d)
n	= modular ratio between beam and deck (4.6.2.2.1)
n_{cf}	= number of intermediate cross-frames or diaphragms within the individual spans of the bridge or bridge unit at the stage of construction being evaluated (4.6.3.3.2)
P	= axle load (kip) (4.6.2.1.3)
P_D	= design horizontal wind pressure specified in Article 3.8.1 (ksf) (C4.6.2.7.1)
P_e	= Euler buckling load (kip) (4.5.3.2.2b)
P_u	= factored axial load (kip) (4.5.3.2.2b) (4.7.4.5)
P_w	= lateral wind force applied to the brace point (kips) (C4.6.2.7.1)
p_e	= equivalent uniform static seismic loading per unit length of bridge that is applied to represent the primary mode of vibration (kip/ft) (C4.7.4.3.2c)
$p_e(x)$	= the intensity of the equivalent static seismic loading that is applied to represent the primary mode of vibration (kip/ft) (C4.7.4.3.2b)
p_o	= a uniform load arbitrarily set equal to 1.0 (kip/ft) (C4.7.4.3.2b)
R	= girder radius (ft); reaction on exterior beam in terms of lanes; minimum radius of curvature at the centerline of the bridge cross-section throughout the length of the bridge or bridge unit at the construction stage and/or loading condition being evaluated (ft); radius of curvature; R -factor specified in Article 3.10.7 (C4.6.1.2.4b) (C4.6.2.2.2d) (4.6.3.3.2) (C4.6.6) (4.7.4.5)
R_d	= factor for calculation of seismic displacements due to inelastic action (4.7.4.5)
r	= reduction factor for longitudinal force effect in skewed bridges (4.6.2.3)
S	= spacing of supporting components (ft); spacing of beams or webs (ft); clear span (ft); skew of support measured from line normal to span (degrees) (4.6.2.1.3) (4.6.2.1.5) (4.6.2.2.1) (4.6.2.10.2) (4.7.4.4)
S_a	= design spectral acceleration coefficient (C4.7.4.3.2b)
S_b	= spacing of grid bars (in.) (4.6.2.1.3)
S_{DS}	= equivalent earthquake response spectral acceleration coefficient at short periods used to determine displacement amplification (4.7.4.5)
S_{D1}	= equivalent 1.0 s acceleration coefficient (4.7.4.5)
SM	= single-mode elastic method (4.7.4.3.1)
s	= length of a side element (in.) (C4.6.2.2.1)
T	= period of fundamental mode of vibration (s) (4.7.4.5)
T_G	= temperature gradient ($\Delta^\circ\text{F}$) (C4.6.6)
TH	= time-history method (4.7.4.3.1)
T_m	= period of m th mode of vibration (sec.) (C4.7.4.3.2b)
T_S	= reference period related to the shape of seismic response spectrum (s) (4.7.4.5)
T_u	= uniform specified temperature ($^\circ\text{F}$) (C4.6.6)
T_{UG}	= temperature averaged across the cross-section ($^\circ\text{F}$) (C4.6.6)
t	= thickness of plate-like element (in.) (C4.6.2.2.1)
t_g	= depth of steel grid or corrugated steel plank including integral concrete overlay or structural concrete component, less a provision for grinding, grooving, or wear (in.) (4.6.2.2.1)
t_o	= depth of structural overlay (in.) (4.6.2.2.1)
t_s	= depth of concrete slab (in.) (4.6.2.2.1) (4.6.2.6.1)
UL	= uniform load elastic method (4.7.4.3.1)
V	= total internal shear acting on a cross-frame panel and an equivalent concrete deck strip computed by 2D grid analysis models utilizing equivalent cross-frame beams (kip) (C4.6.3.3.4a)
V_{CF}	= portion of the total internal shear, V , resisted by a cross-frame panel (kip) (C4.6.3.3.4a)
V_{deck}	= portion of the total internal shear, V , resisted by the concrete deck at a cross-frame (kip) (C4.6.3.3.4a)
V_{LD}	= maximum vertical shear at $3d$ or $L/4$ due to wheel loads distributed laterally as specified herein (kips) (4.6.2.2.2a)
V_{LL}	= distributed live load vertical shear (kips) (4.6.2.2.2a)
V_{LU}	= maximum vertical shear at $3d$ or $L/4$ due to undistributed wheel loads (kips) (4.6.2.2.2a)
$v_s(x)$	= deformation corresponding to p_o (ft) (C4.7.4.3.2b)
$v_{s,MAX}$	= maximum value of $v_s(x)$ (ft) (C4.7.4.3.2c)
W	= edge-to-edge width of bridge (ft); factored wind force per unit length (kip/ft); total weight of cable (kip); total weight of bridge (kip) (4.6.2.2.1) (C4.6.2.7.1) (4.6.3.7) (C4.7.4.3.2c)
W_e	= half the web spacing, plus the total overhang (ft) (4.6.2.2.1)
W_1	= modified edge-to-edge width of bridge taken to be equal to the lesser of the actual width or 60.0 for multilane loading, or 30.0 for single-lane loading (ft) (4.6.2.3)
w	= width of clear roadway (ft); width of element in cross-section (in.) (4.6.2.2.2b) (C4.6.6)

$w(x)$	=	nominal, unfactored dead load of the bridge superstructure and tributary substructure (kip/ft) (C4.7.4.3.2b) (C4.7.4.3.2c)
w_p	=	plank width (in.) (4.6.2.1.3)
w_g	=	maximum width between the girders on the outside of the bridge cross-section at the completion of the construction or at an intermediate stage of the steel erection (ft) (4.6.3.3.2)
X	=	distance from load to point of support (ft) (4.6.2.1.3)
X_{ext}	=	horizontal distance from the center of gravity of the pattern of girders to the exterior girder (ft) (C4.6.2.2.2d)
x	=	horizontal distance from the center of gravity of the pattern of girders to each girder (ft) (C4.6.2.2.2d)
Z	=	a factor taken as 1.20 where the lever rule was not utilized, and 1.0 where the lever rule was used for a single-lane live load distribution factor (4.6.2.2.5)
z	=	vertical distance from center of gravity of cross-section (in.) (C4.6.6)
α	=	angle between cable and horizontal (degrees); coefficient of thermal expansion (in./in./°F); generalized flexibility (4.6.3.7) (C4.6.6) (C4.7.4.3.2b)
β	=	generalized participation (C4.7.4.3.2b)
γ	=	load factor; generalized mass (C4.6.2.7.1) (C4.7.4.3.2b)
Δ	=	displacement of point of contraflexure in column or pier relative to point of fixity for the foundation (in.) (4.7.4.5)
Δ_e	=	displacement calculated from elastic seismic analysis (in.) (4.7.4.5)
Δ_w	=	deck slab overhang width (in.) (4.6.2.6.1)
δ_b	=	moment or stress magnifier for braced mode deflection (4.5.3.2.2b)
δ_s	=	moment or stress magnifier for unbraced mode deflection (4.5.3.2.2b)
ϵ_u	=	uniform axial strain due to axial thermal expansion (in./in.) (C4.6.6)
η_i	=	load modifier relating to ductility, redundancy, and operational importance as specified in Article 1.3.2.1 (C4.6.2.7.1)
θ	=	skew angle (degrees); maximum skew angle of the bearing lines at the end of a given span, measured from a line taken perpendicular to the span centerline (degrees) (4.6.2.2.1) (4.6.3.3.2)
μ	=	Poisson's ratio (4.6.2.2.1)
σ_E	=	internal stress due to thermal effects (ksi) (C4.6.6)
ϕ	=	rotation per unit length; flexural resistance factor (C4.6.6) (4.7.4.5)
ϕ_K	=	stiffness reduction factor = 0.75 for concrete members and 1.0 for steel and aluminum members (4.5.3.2.2b)

4.4—ACCEPTABLE METHODS OF STRUCTURAL ANALYSIS

Any method of analysis that satisfies the requirements of equilibrium and compatibility and utilizes stress-strain relationships for the proposed materials may be used, including, but not limited to:

- classical force and displacement methods,
- finite difference method,
- finite element method,
- folded plate method,
- finite strip method,
- grid analogy method,
- series or other harmonic methods,
- methods based on the formation of plastic hinges, and
- yield line method.

The Designer shall be responsible for the implementation of computer programs used to facilitate structural analysis and for the interpretation and use of results.

C4.4

Many computer programs are available for bridge analysis. Various methods of analysis, ranging from simple formulas to detailed finite element procedures, are implemented in such programs. Many computer programs have specific engineering assumptions embedded in their code, which may or may not be applicable to each specific case.

When using a computer program, the Designer should clearly understand the basic assumptions of the program and the methodology that is implemented. For guidance on developing refined models, FHWA's *Manual for Refined Analysis in Bridge Design and Evaluation* (FHWA-HIF-18-046) is available as a resource.

A computer program is only a tool, and the user is responsible for the generated results. Accordingly, all output should be verified to the extent possible.

Computer programs should be verified against the results of:

- universally accepted closed-form solutions,
- other previously verified computer programs, or
- physical testing.

The name, version, and release date of software used should be indicated in the contract documents.

The purpose of identifying software is to establish code compliance and to provide a means of locating bridges designed with software that may later be found deficient.

4.5—MATHEMATICAL MODELING

4.5.1—General

Mathematical models shall include loads, geometry, material behavior of the structure, and, where appropriate, response characteristics of the foundation. The choice of model shall be based on the limit states investigated, the force effect being quantified, and the accuracy required.

Unless otherwise permitted, consideration of continuous composite barriers shall be limited to service and fatigue limit states and to structural evaluation.

The stiffness of structurally discontinuous railings, curbs, elevated medians, and barriers shall not be considered in structural analysis.

For the purpose of this Section, an appropriate representation of the soil and/or rock that supports the bridge shall be included in the mathematical model of the foundation.

In the case of seismic design, gross soil movement and liquefaction should also be considered.

If lift-off is indicated at a bearing, the analysis shall recognize the vertical freedom of the girder at that bearing.

C4.5.1

Service and fatigue limit states should be analyzed as fully elastic, as should strength limit states, except in cases of certain continuous girders where inelastic analysis is specifically permitted, such as inelastic redistribution of negative bending moment, and stability investigations. The extreme event limit states may require collapse investigation based entirely on inelastic modeling.

Very flexible bridges, e.g., suspension and cable-stayed bridges, should be analyzed using nonlinear elastic methods, such as the large deflection theory.

The need for sophisticated modeling of foundations is a function of the sensitivity of the structure to foundation movements.

In some cases, the foundation model may be as simple as unyielding supports. In other cases, an estimate of settlement may be acceptable. Where the structural response is particularly sensitive to the boundary conditions, such as in a fixed-end arch or in computing natural frequencies, rigorous modeling of the foundation should be made to account for the conditions present. In lieu of rigorous modeling, the boundary conditions may be varied to extreme bounds, such as fixed or free of restraint, and envelopes of force effects considered.

Where lift-off restraints are provided in the contract documents, the construction stage at which the restraints are to be installed should be clearly indicated. The analysis should recognize the vertical freedom of the girder consistent with the construction sequence shown in the contract documents.

4.5.2—Structural Material Behavior

4.5.2.1—Elastic Versus Inelastic Behavior

For the purpose of analysis, structural materials shall be considered to behave linearly up to an elastic limit and inelastically thereafter.

Actions at the extreme event limit state may be accommodated in both the inelastic and elastic ranges.

4.5.2.2—Elastic Behavior

Elastic material properties and characteristics shall be in accordance with the provisions of Sections 5, 6, 7, and 8. Changes in these values due to maturity of concrete and environmental effects should be included in the model where appropriate.

The stiffness properties of concrete and composite members shall be based upon cracked and/or uncracked sections consistent with the anticipated behavior. Stiffness characteristics of beam-slab-type bridges may be based on full participation of concrete decks.

4.5.2.3—Inelastic Behavior

Sections of components that may undergo inelastic deformation shall be shown to be ductile or made ductile by confinement or other means. Where inelastic analysis is used, a preferred design failure mechanism and its attendant hinge locations shall be determined. It shall be ascertained in the analysis that shear, buckling, and bond failures in the structural components do not precede the formation of a flexural inelastic mechanism. Unintended overstrength of a component in which hinging is expected should be considered. Deterioration of geometrical integrity of the structure due to large deformations shall be taken into account.

The inelastic model shall be based either upon the results of physical tests or upon a representation of load-deformation behavior that is validated by tests. Where inelastic behavior is expected to be achieved by confinement, test specimens shall include the elements that provide such confinement. Where extreme force

C4.5.2.2

For beam-slab-type bridges, tests indicate that in the elastic range of structural behavior, cracking of concrete seems to have little effect on the global behavior of bridge structures. This effect can, therefore, be safely neglected by modeling the concrete as uncracked for the purposes of structural analysis (King et al., 1975) (Yen et al., 1995).

Force effects from superimposed deformation such as secondary forces from prestressing, creep, shrinkage, temperature gradient, and uniform temperature change can be significant when using uncracked section properties and assuming unyielding supports. Under the strength limit states, partially cracked piers or columns and foundation flexibility may be anticipated. As such, cracked section properties in columns or piers and foundation flexibility may be considered to reduce the force effects from superimposed deformation. Effective section properties may be calculated using the method recommended in Section 9.6.2.3 of FHWA's *Manual for Refined Analysis in Bridge Design and Evaluation* (FHWA-HIF-18-046).

C4.5.2.3

Where technically possible, the preferred failure mechanism should be based on a response that has generally been observed to provide for large deformations as a means of warning of structural distress.

The selected mechanism should be used to estimate the extreme force effect that can be applied adjacent to a hinge.

Unintended overstrength of a component may result in an adverse formation of a plastic hinge at an undesirable location, forming a different mechanism.

effects are anticipated to be repetitive, the tests shall reflect their cyclic nature.

Except where noted, stresses and deformations shall be based on a linear distribution of strains in the cross-section of prismatic components. Shear deformation of deep components shall be considered. Limits on concrete strain specified in Section 5 shall not be exceeded.

The inelastic behavior of compressive components shall be taken into account, wherever applicable.

4.5.3—Geometry

4.5.3.1—Small-Deflection Theory

If the deformation of the structure does not result in a significant change in force effects due to an increase in the eccentricity of compressive or tensile forces, such secondary force effects may be ignored.

C4.5.3.1

Small-deflection theory is usually adequate for the analysis of beam-type bridges. Bridges which resist loads primarily through a couple whose tensile and compressive forces remain in essentially fixed positions relative to each other while the bridge deflects, such as in trusses and tied arches, are generally insensitive to deformations. Columns and structures in which the flexural moments are increased or decreased by deflection tend to be sensitive to deflection considerations. Such structures include suspension bridges, very flexible cable-stayed bridges, and some arches other than tied arches and frames.

In many cases, the degree of sensitivity can be assessed and evaluated by a single-step approximate method, such as the moment magnification factor method. In the remaining cases, a complete second-order analysis may be necessary.

The past traditional boundary between small- and large deflection theory becomes less distinct as bridges and bridge components become more flexible due to advances in material technology, the change from mandatory to optional deflection limits, and the trend toward more accurate and optimized design. The Engineer needs to consider these aspects in the choice of an analysis method.

Small-deflection elastic behavior permits the use of the principle of superposition and efficient analytical solutions. These assumptions are typically used in bridge analysis for this reason. The behavior of the members assumed in these provisions is generally consistent with this type of analysis.

Superposition does not apply for the analysis of construction processes that include changes in the stiffness of the structure.

Moments from noncomposite and composite analyses may not be added for the purpose of computing stresses. The addition of stresses and deflections due to noncomposite and composite actions computed from separate analyses is appropriate.

4.5.3.2—Large Deflection Theory

4.5.3.2.1—General

If the deformation of the structure results in a significant change in force effects, the effects of

C4.5.3.2.1

A properly formulated large deflection analysis is one that provides all the force effects necessary for the

deformation shall be considered in the equations of equilibrium.

The effect of deformation and out-of-straightness of components shall be included in stability analyses and large deflection analyses.

For slender concrete compressive components, those time- and stress-dependent material characteristics that cause significant changes in structural geometry shall be considered in the analysis.

The interaction effects of tensile and compressive axial forces in adjacent components should be considered in the analysis of frames and trusses.

Only factored loads shall be used and no superposition of force effects shall be applied in the nonlinear range. The order of load application in nonlinear analysis shall be consistent with that on the actual bridge.

design. Further application of moment magnification factors is neither required nor appropriate. The presence of compressive axial forces amplifies both out-of-straightness of a component and the deformation due to nontangential loads acting thereon, thereby increasing the eccentricity of the axial force with respect to the centerline of the component. The synergistic effect of this interaction is the apparent softening of the component, i.e., a loss of stiffness. This is commonly referred to as a second-order effect. The converse is true for tension. As axial compressive stress becomes a higher percentage of the so-called Euler buckling stress, this effect becomes increasingly more significant.

The second-order effect arises from the translation of applied load creating increased eccentricity. It is considered as geometric nonlinearity and is typically addressed by iteratively solving the equilibrium equations or by using geometric stiffness terms in the elastic range (Przemieniecki, 1968). The analyst should be aware of the characteristics of the elements employed, the assumptions upon which they are based, and the numerical procedures used in the computer code. Discussions on the subject are given by White and Hajjar (1991) and Galambos (1998). Both references are related to metal structures, but the theory and applications are generally usable. Both contain numerous additional references that summarize the state-of-the-art in this area.

Because large deflection analysis is inherently nonlinear, the loads are not proportional to the displacements, and superposition cannot be used. This includes force effects due to changes in time-dependent properties, such as creep and shrinkage of concrete. Therefore, the order of load application can be important and traditional approaches, such as influence functions, are not directly applicable. The loads should be applied in the order experienced by the structure, e.g., dead load stages followed by live load stages. If the structure undergoes nonlinear deformation, the loads should be applied incrementally with consideration for the changes in stiffness after each increment.

In conducting nonlinear analysis, it is prudent to perform a linear analysis for a baseline and to use the procedures employed on the problem at hand on a simple structure that can be analyzed by hand, such as a cantilever beam. This permits the analyst to observe behavior and develop insight into behavior that is not easily gained from more complex models.

4.5.3.2.2—Approximate Methods

4.5.3.2.2a—General

Where permitted in Sections 5, 6, and 7, the effects of deflection on force effects on beam columns and arches which meet the provisions of these Specifications may be approximated by the single-step adjustment method known as moment magnification.

C4.5.3.2.2a

The moment magnification procedure outlined herein is one of several variations of the approximate process and was selected as a compromise between accuracy and ease of use. It is believed to be conservative. An alternative procedure thought to be more accurate than the one specified herein may be found in AISC (1993). This alternative procedure will require supplementary calculations not commonly made in bridge design using modern computational methods.

In some cases, the magnitude of movement implied by the moment magnification process cannot be physically attained. For example, the actual movement of a pier may be limited to the distance between the end of longitudinal beams and the backwall of the abutment. In cases where movement is limited, the moment magnification factors of elements so limited may be reduced accordingly.

4.5.3.2.2b—Moment Magnification—Beam Columns

C4.5.3.2.2b

The factored moments or stresses may be increased to reflect effects of deformations as follows:

$$M_c = \delta_b M_{2b} + \delta_s M_{2s} \quad (4.5.3.2.2b-1)$$

$$f_c = \delta_b f_{2b} + \delta_s f_{2s} \quad (4.5.3.2.2b-2)$$

in which:

$$\delta_b = \frac{C_m}{1 - \frac{P_u}{\phi_K P_e}} \geq 1.0 \quad (4.5.3.2.2b-3)$$

$$\delta_s = \frac{1}{1 - \frac{\Sigma P_u}{\phi_K \Sigma P_e}} \quad (4.5.3.2.2b-4)$$

where:

M_c = factored moment, corrected to account for second-order effects (kip-ft)

M_{2b} = moment on compression member due to factored gravity loads that result in no appreciable sidesway calculated by conventional first-order elastic frame analysis; always positive (kip-ft)

M_{2s} = moment on compression member due to factored lateral or gravity loads that result in sidesway, Δ , greater than $\ell_u/1,500$, calculated by conventional first-order elastic frame analysis; always positive (kip-ft)

- f_c = factored stress, corrected to account for second-order effects (ksi)
 f_{2b} = stress corresponding to M_{2b} (ksi)
 f_{2s} = stress corresponding to M_{2s} (ksi)
 P_u = factored axial load (kip)
 ϕ_K = stiffness reduction factor; 0.75 for concrete members and 1.0 for steel, concrete-filled steel tubes, and aluminum members
 P_e = Euler buckling load (kip)

For steel/concrete composite columns, the Euler buckling load, P_e , shall be determined as specified in Article 6.9.5.1. For all other cases, P_e shall be taken as:

$$P_e = \frac{\pi^2 EI}{(K \ell_u)^2} \quad (4.5.3.2.2b-5)$$

where:

- E = modulus of elasticity (ksi)
 I = moment of inertia about axis under consideration (in.⁴)
 K = effective length factor in the plane of bending as specified in Article 4.6.2.5. For calculation of δ_b , P_e shall be based on the K -factor for braced frames; for calculation of δ_s , P_e shall be based on the K -factor for unbraced frames
 ℓ_u = unsupported length of a compression member (in.)

For concrete compression members, the provisions of Article 5.6.4.3 also apply.

For members braced against sidesway, δ_s shall be taken as 1.0 unless analysis indicates that a lower value may be used. For members not braced against sidesway, δ_b shall be determined as for a braced member and δ_s for an unbraced member.

For members braced against sidesway and without transverse loads between supports, the moment gradient coefficient, C_m , may be taken as:

$$C_m = 0.6 + 0.4 \frac{M_{1b}}{M_{2b}} \quad (4.5.3.2.2b-6)$$

The previous limit $C_m \geq 0.4$ has been shown to be unnecessary in AISC (1994), Chapter C commentary.

where:

- M_{1b} = smaller factored end moment
 M_{2b} = larger factored end moment

The ratio M_{1b}/M_{2b} is considered positive if the component is bent in single curvature and negative if it is bent in double curvature.

For all other cases, C_m shall be taken as 1.0.

In structures that are not braced against sidesway, the flexural members and foundation units framing into the compression member shall be designed for the sum of end moments of the compression member at the joint.

Where compression members are subject to flexure about both principal axes, the moment about each axis

shall be magnified by δ , determined from the corresponding conditions of restraint about that axis.

Where a group of compression members on one level comprise a bent, or where they are connected integrally to the same superstructure, and collectively resist the sidesway of the structure, the value of δ_s shall be computed for the member group with ΣP_u and ΣP_e equal to the summations for all columns in the group.

4.5.3.2.2c—Moment Magnification—Arches

Live load and impact moments from a small-deflection analysis shall be increased by the moment magnification factor, δ_b , as specified in Article 4.5.3.2.2b, with the following definitions:

ℓ_u = one-half of the length of the arch rib (in.)
 K = effective length factor specified in Table 4.5.3.2.2c-1
 C_m = 1.0

Table 4.5.3.2.2c-1— K Values for Effective Length of Arch Ribs

Rise-to-Span Ratio	3-Hinged Arch	2-Hinged Arch	Fixed Arch
0.1–0.2	1.16	1.04	0.70
0.2–0.3	1.13	1.10	0.70
0.3–0.4	1.16	1.16	0.72

4.5.3.2.3—Refined Methods

Refined methods of analysis shall be based upon the concept of forces satisfying equilibrium in a deformed position.

C4.5.3.2.3

Flexural equilibrium in a deformed position may be iteratively satisfied by solving a set of simultaneous equations, or by evaluating a closed-form solution formulated using the displaced shape.

4.5.4—Modeling Boundary Conditions

Boundary conditions shall represent actual characteristics of support and continuity.

Foundation conditions shall be modeled in such a manner as to represent the soil properties underlying the bridge, the soil–pile interaction, and the elastic properties of piles.

C4.5.4

If the accurate assessment of boundary conditions cannot be made, their effects may be bounded.

4.5.5—Equivalent Members

Nonprismatic components may be modeled by discretizing the components into a number of frame elements with stiffness properties representative of the actual structure at the location of the element.

Components or groups of components of bridges with or without variable cross-sections may be modeled as a single equivalent component provided that it represents all the stiffness properties of the components or group of components. The equivalent stiffness properties may be obtained by closed-form solutions, numerical integration, submodel analysis, and series and parallel analogies.

C4.5.5

Standard frame elements in available analysis programs may be used. The number of elements required to model the nonprismatic variation is dependent on the type of behavior being modeled, e.g., static, dynamic, or stability analysis. Typically, eight elements per span will give sufficient accuracy for actions in a beam loaded statically with cross-sectional properties that vary smoothly. Fewer elements are required to model for deflection and frequency analyses.

Alternatively, elements may be used that are based on the assumed tapers and cross-sections. Karabalis (1983) provides a comprehensive examination of this issue. Explicit forms of stiffness coefficients are given for linearly tapered rectangular, flanged, and box sections. Aristizabal (1987) presents similar equations in a simple format that can be readily implemented into stiffness-based computer programs. Significant bibliographies are given in Karabalis (1983) and Aristizabal (1987).

4.6—STATIC ANALYSIS

4.6.1—Influence of Plan Geometry

4.6.1.1—Plan Aspect Ratio

If the span length of a superstructure with torsionally stiff closed cross-sections exceeds 2.5 times its width, the superstructure may be idealized as a single-spine beam. The following dimensional definitions shall be used to apply this criterion:

- Width—the core width of a monolithic deck or the average distance between the outside faces of exterior web.
- Length for rectangular simply supported bridges—the distance between deck joints.
- Length for continuous and/or skewed bridges—the length of the longest side of the rectangle that can be drawn within the plan view of the width of the smallest span, as defined herein.
- The length-to-width restriction specified above does not apply to concrete box girder bridges.

C4.6.1.1

Where transverse distortion of a superstructure is small in comparison with longitudinal deformation, the former does not significantly affect load distribution, hence, an equivalent beam idealization is appropriate. The relative transverse distortion is a function of the ratio between structural width and height; the latter, in turn, depending on the length. Hence, the limits of such idealization are determined in terms of the width-to-effective length ratio.

Simultaneous torsion, moment, shear, and reaction forces and the attendant stresses are to be superimposed as appropriate. The equivalent beam idealization does not alleviate the need to investigate warping effects in steel structures. In all equivalent beam idealizations, the eccentricity of loads should be taken with respect to the centerline of the equivalent beam. Asymmetrical sections need to consider the relative location of the shear center and center of gravity.

4.6.1.2—Structures Curved in Plan

4.6.1.2.1—General

The moments, shears, and other force effects required to proportion the superstructure components shall be based on a rational analysis of the entire superstructure. Analysis of sections with no axis of symmetry should consider the relative locations of the

C4.6.1.2.1

Since equilibrium of horizontally curved I-girders is developed by the transfer of load between the girders, the analysis must recognize the integrated behavior of all structural components. Equilibrium of curved box girders may be less dependent on the interaction

center of gravity and the shear center. The substructure shall also be considered in the case of integral abutments, piers, or bents.

The entire superstructure, including bearings, shall be considered as an integral structural unit. Boundary conditions shall represent the articulations provided by the bearings, integral connections used in the design, or both. Analyses may be based on elastic small-deflection theory, unless more rigorous approaches are deemed necessary by the Engineer.

Analyses shall consider bearing orientation and restraint of bearings afforded by the substructure. These load effects shall be considered in designing bearings, cross-frames, diaphragms, bracing, and the deck.

Distortion of the cross-section need not be considered in the structural analysis.

Centrifugal force effects shall be considered in accordance with Article 3.6.3.

4.6.1.2.2—Single-Girder Torsionally Stiff Superstructures

Except for concrete box girder bridges, a horizontally curved, torsionally stiff single-girder superstructure meeting the requirements of Article 4.6.1.1 may be analyzed for global force effects as a curved spine beam.

The location of the centerline of such a beam shall be taken at the center of gravity of the cross-section, and the eccentricity of dead loads shall be established by volumetric consideration.

4.6.1.2.3—Concrete Box Girder Bridges

Horizontally curved concrete box girders may be designed with straight segments, for central angles up to 12 degrees within one span, unless concerns about other force effects dictate otherwise.

Horizontally curved nonsegmental concrete box girder bridge superstructures may be analyzed and designed for global force effects as single-spine beams with straight segments for central angles up to 34 degrees within one span as shown in Figure 4.6.1.2.3-1, unless concerns about local force effects dictate otherwise. The location of the centerline of such a beam shall be taken at the center of gravity of the cross-section and the eccentricity of dead loads shall be established by volumetric consideration. Where the substructure is integral with the superstructure, the substructure elements shall be included in the model and allowance made for prestress friction loss due to horizontal curvature or tendon deviation.

between girders. Bracing members are considered primary members in curved bridges since they transmit forces necessary to provide equilibrium.

The deck acts in flexure, vertical shear, and horizontal shear. Torsion increases the horizontal deck shear, particularly in curved box girders. The lateral restraint of the bearings may also cause horizontal shear in the deck.

Small-deflection theory is adequate for the analysis of most curved-girder bridges. However, curved I-girders are prone to deflect laterally when the girders are insufficiently braced during erection. This behavior may not be well recognized by small-deflection theory.

Classical methods of analysis are usually based on strength-of-materials assumptions that do not recognize cross-section deformation. Finite element analyses that model the actual cross-section shape of the I- or box girders can recognize cross-section distortion and its effect on structural behavior. Cross-section deformation of steel box girders may have a significant effect on torsional behavior, but this effect is limited by the provision of sufficient internal cross-bracing.

C4.6.1.2.2

In order to apply the aspect ratio provisions of Article 4.6.1.1, as specified, the plan needs to be hypothetically straightened. Force effects should be calculated on the basis of the actual curved layout.

With symmetrical cross-sections, the center of gravity of permanent loads falls outside the center of gravity. Shear center of the cross-section and the resulting eccentricity need to be investigated.

C4.6.1.2.3

Concrete box girders generally behave as a single-girder multi-web torsionally stiff superstructure. A parameter study conducted by Song, Chai, and Hida (2003) indicated that the distribution factors from the Load and Resistance Factor Design (LRFD) formulas compared well with the distribution factors from grid analyses when using straight segments on spans with central angles up to 34 degrees in one span.

Nutt, Redfield, and Valentine (2008) studied the limits of applicability for various methods of analyzing horizontally curved concrete box girder bridges. The focus of this study was on local as well as global force effects. They identified three approaches for the analysis of concrete box girder bridges as follows:

- The first method allows bridges with a central angle within one span of less than 12 degrees to be analyzed as if they were straight because curvature has a minor

effect on response. This is typically done with a plane frame analysis.

- The second method involves a spine beam analysis, in which the superstructure is idealized as a series of straight beam chorded segments of limited central angle located along the bridge centerline. Where the substructure is integral with the superstructure, a space frame analysis is required. Whole-width design as described in Article 4.6.2.2.1 was found to yield conservative results when space frame analysis was used. It is acceptable to reduce the number of live load lanes applied to the whole-width model to those that can fit on the bridge when global response such as torsion or transverse bending is being considered.
- Bridges with high curvatures or unusual plan geometry require a third method of analysis that utilizes sophisticated three-dimensional computer models. Unusual plan geometry includes, but is not limited to, bridges with variable widths or with unconventional orientation of skewed supports.

The range of applicability using approximate methods herein is expected to yield results within five percent of the most detailed type of analysis. Analysis of force effects in curved tendons is also addressed in Article 5.9.5.4.3.

Figure 4.6.1.2.3-1—Definition of Central Angle

Horizontally curved segmental concrete box girder superstructures meeting the requirements of Article 4.6.1.1, and whose central angle within one span is between 12 degrees and 34 degrees, may be analyzed as a single-spine beam comprised of straight segments provided no segment has a central angle greater than 3.5 degrees as shown in Figure 4.6.1.2.3-2. For integral substructures, an appropriate three-dimensional model of the structure shall be used. Redistribution of forces due to the time-dependent properties of concrete shall be accounted for.

Figure 4.6.1.2.3-2—Three-Dimensional Spine Model of Curved Concrete Box Girder Bridge

For both segmental and nonsegmental box girder bridges with central angles exceeding 34 degrees within any one span or for bridges with a maximum central angle in excess of 12 degrees with unusual plan geometry, the bridge shall be analyzed using six degrees-of-freedom in a proven three-dimensional analysis method.

4.6.1.2.4—Steel Multiple-Beam Superstructures

4.6.1.2.4a—General

Horizontally curved superstructures may be analyzed as grids or continuums in which the segments of the longitudinal beams are assumed to be straight between nodes. The actual eccentricity of the segment between the nodes shall not exceed 2.5 percent of the length of the segment.

4.6.1.2.4b—I-Girders

The effect of curvature on stability shall be considered for all curved I-girders.

Where I-girder bridges meet the following four conditions, the effects of curvature may be ignored in the analysis for determining the major-axis bending moments and bending shears:

C4.6.1.2.4a

An eccentricity of 2.5 percent of the length of the segment corresponds to a central angle subtended by a curved segment of about 12 degrees.

This Article applies only to major-axis bending moment and does not apply to lateral flange bending or torsion, which should always be examined with respect to curvature.

Bridges with even slight curvature may develop large radial forces at the abutment bearings. Therefore, thermal analysis of all curved bridges is recommended.

C4.6.1.2.4b

The requirement for similar stiffness among the girders is intended to avoid large and irregular changes in stiffness which could alter transverse distribution of load. Under such conditions, a refined analysis would be appropriate. Noncomposite dead load preferably is to be distributed uniformly to the girders since the cross-frames provide restoring forces that prevent the girders

- girders are concentric;
- bearing lines are not skewed more than 10 degrees from radial;
- the stiffnesses of the girders are similar;
- for all spans, the arc span divided by the girder radius in feet is less than 0.06 radians where the arc span, L_{as} , shall be taken as follows:

For simple spans:

$$L_{as} = \text{arc length of the girder (ft)}$$

For end spans of continuous members:

$$L_{as} = 0.9 \text{ times the arc length of the girder (ft)}$$

For interior spans of continuous members:

$$L_{as} = 0.8 \text{ times the arc length of the girder (ft)}$$

An I-girder in a bridge satisfying these criteria may be analyzed as an individual straight girder with span length equal to the arc length. Cross-frame or diaphragm spacing shall be set to limit flange lateral bending effects in the girder, which may be determined from an appropriate approximation. The cross-frame or diaphragm spacing shall also satisfy Eq. 6.7.4.2.1-1. Cross-frames or diaphragms and their connections shall be designed in accordance with the applicable provisions of Articles 6.7.4.2 and 6.13. At a minimum, cross-frame or diaphragms shall be designed to transfer wind loads according to the provisions of Article 4.6.2.7 to meet all slenderness requirements specified in Articles 6.8.4 or 6.9.3, as applicable, and to satisfy the stability bracing stiffness and strength requirements specified in Article 6.7.4.2.2.

from deflecting independently. Certain dead loads applied to the composite bridge may be distributed uniformly to the girders as provided in Article 4.6.2.2.1. However, heavier concentrated line loads such as parapets, sidewalks, barriers, or sound walls should not be distributed equally to the girders. Engineering judgment must be used in determining the distribution of these loads. Often the largest portion of the load on an overhang is assigned to the exterior girder, or to the exterior girder and the first interior girder. The exterior girder on the outside of the curve is often critical in curved girder bridges.

The effect of curvature on the stability of a girder must be considered regardless of the amount of curvature since stability of curved girders is different from that of straight girders (Hall et al., 1999).

In lieu of a refined analysis, Eq. C4.6.1.2.4b-1 may be appropriate for determining the lateral bending moment in I-girder flanges due to curvature (Richardson, Gordon and Associates, 1976) (United States Steel, 1984).

$$M_{lat} = \frac{M \ell^2}{NRD} \quad (\text{C4.6.1.2.4b-1})$$

where:

- M_{lat} = flange lateral bending moment (kip-ft)
- M = major-axis bending moment (kip-ft)
- ℓ = unbraced length (ft)
- N = a constant taken as 10 or 12 in past practice
- R = girder radius (ft)
- D = web depth (ft)

Although the depth to be used in computing the flange lateral moment from Eq. C4.6.1.2.4b-1 is theoretically equal to the depth, h , between the midthickness of the top and bottom flanges, for simplicity, the web depth, D , is conservatively used in Eq. C4.6.1.2.4b-1. The Engineer may substitute the depth, h , for D in Eq. C4.6.1.2.4b-1, if desired. Eq. C4.6.1.2.4b-1 assumes the presence of a cross-frame at the point under investigation, that the cross-frame

4.6.1.2.4c—Closed-Box and Tub Girders

The effect of curvature on strength and stability shall be considered for all curved box girders.

Where box girder bridges meet the following three conditions, the effect of curvature may be ignored in the analysis for determination of the major-axis bending moments and bending shears:

- girders are concentric;
- bearings are not skewed; and
- for all spans, the arc span divided by the girder radius is less than 0.3 radians, and the girder depth is less than the width of the box at mid-depth where the arc span, L_{as} , shall be taken as defined in Article 4.6.1.2.4b.

A box girder in a bridge satisfying these criteria may be analyzed as an individual straight girder with span length equal to the arc length. Internal cross-frame or diaphragm spacing shall be set to limit flange lateral bending effects in the top flanges of a tub girder, which may be determined from an appropriate approximation (Fan and Helwig, 1999), before the deck hardens or is made composite. The spacing of internal cross-frames or diaphragms shall not exceed 40.0 ft. Transverse bending stresses and longitudinal warping stresses due to cross-section distortion may be neglected. Cross-frames and diaphragms and their connections shall be designed in accordance with the applicable provisions of Articles 6.7.4.3 and 6.13. Cross-frame members shall meet all applicable slenderness requirements specified in Articles 6.8.4 or 6.9.3.

Lateral bracing members shall be designed in accordance with Articles 6.7.5 and 6.13 for forces computed by rational means.

4.6.2—Approximate Methods of Analysis

4.6.2.1—Decks

4.6.2.1.1—General

An approximate method of analysis in which the deck is subdivided into strips perpendicular to the

spacing is relatively uniform, and that the major-axis bending moment, M , is constant between brace points. Therefore, at points not actually located at cross-frames, flange lateral moments from Eq. C4.6.1.2.4b-1 may not be strictly correct. The constant, N , in Eq. C4.6.1.2.4b-1 has been taken as either 10 or 12 in past practice and either value is considered acceptable depending on the level of conservatism that is desired.

Other conditions that produce torsion, such as skew, should be dealt with by other analytical means which generally involve a refined analysis.

C4.6.1.2.4c

Although box-shaped girders have not been examined as carefully as I-girders with regard to approximate methods, bending moments in closed girders are less affected by curvature than are I-girders (Tung and Fountain, 1970). However, in a box shape, torsion is much greater than in an open shape so that web shears are affected by torsion due to curvature, skew, or loads applied away from the shear center of the box. Double bearings resist significant torque compared to a box-centered single bearing.

If the box is haunched or tapered, the shallowest girder depth should be used in conjunction with the narrowest width of the box at mid-depth in determining whether the effects of curvature may be ignored in calculating the major-axis bending moments and bending shears.

Fan and Helwig (1999) provide an approach for approximating top flange lateral bracing forces in tub girders in lieu of a refined analysis.

C4.6.2.1.1

In determining the strip widths, the effects of flexure in the secondary direction and of torsion on the

supporting components shall be considered acceptable for decks other than:

- fully filled and partially filled grids for which the provisions of Article 4.6.2.1.8 shall apply, and
- top slabs of segmental concrete box girders for which the provisions of Article 4.6.2.9.4 shall apply.

Where the strip method is used, the extreme positive moment in any deck panel between girders shall be taken to apply to all positive moment regions. Similarly, the extreme negative moment over any beam or girder shall be taken to apply to all negative moment regions.

distribution of internal force effects are accounted for to obtain flexural force effects approximating those that would be provided by a more refined method of analysis.

Depending on the type of deck, modeling and design in the secondary direction may utilize one of the following approximations:

- secondary strip designed in a manner like the primary strip, with all the limit states applicable;
- resistance requirements in the secondary direction determined as a percentage of those in the primary one as specified in Article 9.7.3.2 (i.e., the traditional approach for reinforced concrete slab in the *AASHTO Standard Specifications for Highway Bridges*); or
- minimum structural and/or geometry requirements specified for the secondary direction independent of actual force effects, as is the case for most wood decks.

The approximate strip model for decks is based on rectangular layouts. Currently about two-thirds of all bridges nationwide are skewed. While skew generally tends to decrease extreme force effects, it produces negative moments at corners, torsional moments in the end zones, substantial redistribution of reaction forces, and a number of other structural phenomena that should be considered in the design.

4.6.2.1.2—Applicability

The use of design aids for decks containing prefabricated elements may be permitted in lieu of analysis if the performance of the deck is documented and supported by sufficient technical evidence. The Engineer shall be responsible for the accuracy and implementation of any design aids used.

For slab bridges and concrete slabs spanning more than 15.0 ft and which span primarily in the direction parallel to traffic, the provisions of Article 4.6.2.3 shall apply.

4.6.2.1.3—Width of Equivalent Interior Strips

The width of the equivalent strip of a deck may be taken as specified in Table 4.6.2.1.3-1. Where decks span primarily in the direction parallel to traffic, strips supporting an axle load shall not be taken to be greater than 40.0 in. for open grids and not greater than 144 in. for all other decks where multilane loading is being investigated. For deck overhangs, where applicable, the provisions of Article 3.6.1.3.4 may be used in lieu of the strip width specified in Table 4.6.2.1.3-1 for deck overhangs. The equivalent strips for decks that span primarily in the transverse direction shall not be subject to width limits. The following notation shall apply to Table 4.6.2.1.3-1:

C4.6.2.1.3

Values provided for equivalent strip widths and strength requirements in the secondary direction are based on past experience. Practical experience and future research work may lead to refinement.

To get the load per unit width of the equivalent strip, divide the total load on one design traffic lane by the calculated strip width.

- S = spacing of supporting components (ft)
 h = depth of deck (in.)
 L = span length of deck (ft)
 P = axle load (kip)
 S_b = spacing of grid bars (in.)
 $+M$ = positive moment
 $-M$ = negative moment
 X = distance from load to point of support (ft)

Table 4.6.2.1.3-1—Equivalent Strips

Type of Deck	Direction of Primary Strip Relative to Traffic	Width of Primary Strip (in.)
Concrete:		
Cast-in-place	Overhang	$45.0 + 10.0X$
	Either Parallel or Perpendicular	$+M: 26.0 + 6.6S$ $-M: 48.0 + 3.0S$
Cast-in-place with stay-in-place concrete formwork	Either Parallel or Perpendicular	$+M: 26.0 + 6.6S$ $-M: 48.0 + 3.0S$
Precast, post-tensioned	Either Parallel or Perpendicular	$+M: 26.0 + 6.6S$ $-M: 48.0 + 3.0S$
Steel:		
Open grid	Main Bars	$1.25P + 4.0S_b$
Filled or partially filled grid	Main Bars	Article 4.6.2.1.8 applies
Unfilled, composite grids	Main Bars	Article 4.6.2.1.8 applies
Wood:		
- Prefabricated glulam - Noninterconnected	Parallel Perpendicular	$2.0h + 30.0$ $2.0h + 40.0$
- Interconnected	Parallel Perpendicular	$90.0 + 0.84L$ $4.0h + 30.0$
Stress-laminated	Parallel Perpendicular	$0.8S + 108.0$ $10.0S + 24.0$
- Spike-laminated - Continuous decks or interconnected panels	Parallel Perpendicular	$2.0h + 30.0$ $4.0h + 40.0$
- Noninterconnected panels	Parallel Perpendicular	$2.0h + 30.0$ $2.0h + 40.0$

Wood plank decks shall be designed for the wheel load of the design truck distributed over the tire contact area. For transverse planks, i.e., planks perpendicular to traffic direction:

Only the wheel load is specified for plank decks. Addition of lane load will cause a negligible increase in force effects; however, it may be added for uniformity of the design live load in these Specifications.

- If $w_p \geq 10.0$ in., the full plank width shall be assumed to carry the wheel load.
- If $w_p < 10.0$ in., the portion of the wheel load carried by a plank shall be determined as the ratio of w_p and 10.0 in.

For longitudinal planks:

- If $w_p \geq 20.0$ in., the full plank width shall be assumed to carry the wheel load.
- If $w_p < 20.0$ in., the portion of the wheel load carried by a plank shall be determined as the ratio of w_p and 20.0 in.

where:

w_p = plank width (in.)

4.6.2.1.4—Width of Equivalent Strips at Edges of Slabs

4.6.2.1.4a—General

For the purpose of design, the notional edgebeam shall be taken as a reduced deck strip width specified herein. Any additional integral local thickening or similar protrusion acting as a stiffener to the deck that is located within the reduced deck strip width can be assumed to act with the reduced deck strip width as the notional edgebeam.

4.6.2.1.4b—Longitudinal Edges

Edgebeams shall be assumed to support one line of wheels and, where appropriate, a tributary portion of the design lane load.

Where decks span primarily in the direction of traffic, the effective width of a strip, with or without an edgebeam, may be taken as the sum of the distance between the edge of the deck and the inside face of the barrier, plus 12.0 in., plus one-quarter of the strip width, specified in either Article 4.6.2.1.3, Article 4.6.2.3, or Article 4.6.2.10, as appropriate, but not exceeding either one-half the full strip width or 72.0 in.

4.6.2.1.4c—Transverse Edges

Transverse edgebeams shall be assumed to support one axle of the design truck in one or more design lanes, positioned to produce maximum load effects. Multiple presence factors and the dynamic load allowance shall apply.

The effective width of a strip, with or without an edgebeam, may be taken as the sum of the distance between the transverse edge of the deck and the centerline of the first line of support for the deck, usually taken as a girder web, plus one-half of the width of strip as specified in Article 4.6.2.1.3. The effective width shall not exceed the full strip width specified in Article 4.6.2.1.3.

C4.6.2.1.4c

For decks covered by Table A4-1, the total moment acting on the edgebeam, including the multiple presence factor and the dynamic load allowance, may be calculated by multiplying the moment per unit width, taken from Table A4-1, by the corresponding full strip width specified in Article 4.6.2.1.3.

4.6.2.1.5—Distribution of Wheel Loads

If the spacing of supporting components in the secondary direction exceeds 1.5 times the spacing in the primary direction, all of the wheel loads shall be considered to be applied to the primary strip and the provisions of Article 9.7.3.2 may be applied to the secondary direction.

If the spacing of supporting components in the secondary direction is less than or equal to 1.5 times the spacing in the primary direction, the deck shall be modeled as a system of intersecting strips.

The width of the equivalent strips in both directions may be taken as specified in Table 4.6.2.1.3-1. Each wheel load shall be distributed between two intersecting strips. The distribution shall be determined as the ratio between the stiffness of the strip and the sum of stiffnesses of the intersecting strips. In the absence of more precise calculations, the strip stiffness, k_s , may be estimated as:

$$k_s = \frac{EI_s}{S^3} \quad (4.6.2.1.5-1)$$

where:

- I_s = moment of inertia of the equivalent strip (in.⁴)
 S = spacing of supporting components (in.)

4.6.2.1.6—Calculation of Force Effects

The strips shall be treated as continuous beams or simply supported beams as appropriate. Span length shall be taken as the center-to-center distance between the supporting components. For the purpose of determining force effects in the strip, the supporting components shall be assumed to be infinitely rigid.

The wheel loads may be modeled as concentrated loads or as patch loads whose length along the span shall be the length of the tire contact area, as specified in Article 3.6.1.2.5, plus the depth of the deck. The strips should be analyzed by classical beam theory.

The design section for negative moments and shear forces, where investigated, may be taken as follows:

- For monolithic construction, closed steel boxes, closed concrete boxes, open concrete boxes without top flanges, and stemmed precast beams, i.e., cross-sections (b), (c), (d), (e), (f), (g), (h), (i), and (j) from Table 4.6.2.2.1-1, at the face of the supporting component,
- For steel I-beams and steel tub girders, i.e., cross-sections (a) and (c) from Table 4.6.2.2.1-1, one-quarter the flange width from the centerline of support,

C4.6.2.1.5

This Article attempts to clarify the application of the traditional AASHTO approach with respect to continuous decks.

C4.6.2.1.6

This is a deviation from the traditional approach based on a continuity correction applied to results obtained for analysis of simply supported spans. In lieu of more precise calculations, the unfactored design live load moments for many practical concrete deck slabs can be found in Table A4-1.

For short spans, the force effects calculated using the footprint could be significantly lower, and more realistic, than force effects calculated using concentrated loads.

Reduction in negative moment and shear replaces the effect of reduced span length in the current code. The design sections indicated may be applied to deck overhangs and to portions of decks between stringers or similar lines of support.

Past practice has been to not check shear in typical decks. A design section for shear is provided for use in nontraditional situations. It is not the intent to investigate shear in every deck.

- For precast I-shaped concrete beams and open concrete boxes with top flanges, i.e., cross-sections (c) and (k) from Table 4.6.2.2.1-1, one-third the flange width, but not exceeding 15.0 in., from the centerline of support,
- For wood beams, i.e., cross-section (l) from Table 4.6.2.2.1-1, one-fourth the top beam width from centerline of beam.

For open box beams, each web shall be considered as a separate supporting component for the deck. The distance from the centerline of each web and the adjacent design sections for negative moment shall be determined based on the type of construction of the box and the shape of the top of the web using the requirements outlined above.

4.6.2.1.7—Cross-Sectional Frame Action

Where decks are an integral part of box or cellular cross-sections, flexural and/or torsional stiffnesses of supporting components of the cross-section, i.e., the webs and bottom flange, are likely to cause significant force effects in the deck. Those components shall be included in the analysis of the deck.

If the length of a frame segment is modeled as the width of an equivalent strip, provisions of Articles 4.6.2.1.3, 4.6.2.1.5, and 4.6.2.1.6 may be used.

C4.6.2.1.7

The model used is essentially a transverse segmental strip, in which flexural continuity provided by the webs and bottom flange is included. Such modeling is restricted to closed cross-sections only. In open-framed structures, a degree of transverse frame action also exists, but it can be determined only by complex, refined analysis.

In normal beam-slab superstructures, cross-sectional frame action may safely be neglected. If the slab is supported by box beams or is integrated into a cellular cross-section, the effects of frame action could be considerable. Such action usually decreases positive moments, but may increase negative moments resulting in cracking of the deck. For larger structures, a three-dimensional analysis may be appropriate. For smaller structures, the analysis could be restricted to a segment of the bridge whose length is the width of an equivalent strip.

Extreme force effects may be calculated by combining the:

- longitudinal response of the superstructure approximated by classical beam theory, and
- transverse flexural response modeled as a cross-sectional frame.

4.6.2.1.8—Live Load Force Effects for Fully and Partially Filled Grids and for Unfilled Grid Decks Composite with Reinforced Concrete Slabs

Moments in kip-in./in. of deck due to live load may be determined as:

- Main bars perpendicular to traffic:
For $L \leq 120$ in.

C4.6.2.1.8

The moment equations are based on orthotropic plate theory considering vehicular live loads specified in Article 3.6. The equations take into account relevant factored load combinations, including truck and tandem loads. The moment equations also account for dynamic load allowance, multiple presence factors, and load

$$M_{\text{transverse}} = 1.28D^{0.197}L^{0.459}C \quad (4.6.2.1.8-1)$$

For $L > 120$ in.

$$M_{\text{transverse}} = \frac{D^{0.188}(3.7L^{1.35} - 956.3)}{L}(C) \quad (4.6.2.1.8-2)$$

- Main bars parallel to traffic:

For $L \leq 120$ in.

$$M_{\text{parallel}} = 0.73D^{0.123}L^{0.64}C \quad (4.6.2.1.8-3)$$

For $L > 120$ in.

$$M_{\text{parallel}} = \frac{D^{0.138}(3.1L^{1.429} - 1088.5)}{L}(C) \quad (4.6.2.1.8-4)$$

where:

- L = span length from center-to-center of supports (in.)
- C = continuity factor; 1.0 for simply supported and 0.8 for continuous spans
- D = D_x/D_y
- D_x = flexural rigidity of deck in main bar direction (kip-in.²/in.)
- D_y = flexural rigidity of deck perpendicular to main bar direction (kip-in.²/in.)

For grid decks, D_x and D_y should be calculated as EI_x and EI_y , where E is the modulus of elasticity and I_x and I_y are the moments of inertia per unit width of deck, considering the section as cracked and using the transformed area method to calculate the flexural rigidity, EI , in each direction.

Moments for fatigue assessment may be estimated for all span lengths by reducing Eq. 4.6.2.1.8-1 for main bars perpendicular to traffic, or Eq. 4.6.2.1.8-3 for main bars parallel to traffic by a factor of 1.5.

Deflection in units of in. due to vehicular live load may be determined as:

- Main bars perpendicular to traffic:

$$\Delta_{\text{transverse}} = \frac{0.0052D^{0.19}L^3}{D_x} \quad (4.6.2.1.8-5)$$

- Main bars parallel to traffic:

$$\Delta_{\text{parallel}} = \frac{0.0072D^{0.11}L^3}{D_x} \quad (4.6.2.1.8-6)$$

positioning on the deck surface to produce the largest possible moment.

Negative moment can be determined as maximum simple span positive moment times the continuity factor, C .

The reduction factor of 1.5 given in Article 4.6.2.1.8 accounts for smaller dynamic load allowance (15 percent vs. 33 percent), smaller load factor (1.50 vs. 1.75) and no multiple presence (1.0 vs. 1.2) when considering the Fatigue I limit state. Use of Eqs. 4.6.2.1.8-1 and 4.6.2.1.8-3 for all spans is appropriate as Eqs. 4.6.2.1.8-1 and 4.6.2.1.8-3 reflect an individual design truck on short span lengths while Eqs. 4.6.2.1.8-2 and 4.6.2.1.8-4 reflect the influence of multiple design tandems that control moment envelope on longer span lengths. The approximation produces reasonable estimates of fatigue moments, however, improved estimates can be determined using fatigue truck patch loads in the infinite series formula provided by Higgins (2003).

Actual D_x and D_y values can vary considerably depending on the specific deck design, and using assumed values based only on the general type of deck can lead to unconservative design moments. Flexural rigidity in each direction should be calculated analytically as EI considering the section as cracked and using the transformed area method.

The deflection equations permit calculation of the mid-span displacement for a deck under service load. The equations are based on orthotropic plate theory and consider both truck and tandem loads on a simply supported deck.

Deflection may be reduced for decks continuous over three or more supports. A reduction factor of 0.8 is conservative.

4.6.2.1.9—Inelastic Analysis

Inelastic finite element analysis or yield line analysis may be permitted by the Owner.

4.6.2.2—Beam-Slab Bridges

4.6.2.2.1—Application

The provisions of this Article may be applied to straight girder bridges and horizontally curved concrete bridges, as well as horizontally curved steel girder bridges complying with the provisions of Article 4.6.1.2.4. The provisions of this Article may also be used to determine a starting point for some methods of analysis to determine force effects in curved girders of any degree of curvature in plan.

Except as specified in Article 4.6.2.2.5, the provisions of this Article shall be taken to apply to bridges being analyzed for:

- a single lane of loading, or
- multiple lanes of live load yielding approximately the same force effect per lane.

If one lane is loaded with a special vehicle or evaluation permit vehicle, the design force effect per girder resulting from the mixed traffic may be determined as specified in Article 4.6.2.2.5.

For beam spacing exceeding the range of applicability as specified in tables in Articles 4.6.2.2.2 and 4.6.2.2.3, the live load on each beam shall be the reaction of the loaded lanes based on the lever rule unless specified otherwise herein.

The provisions of Article 3.6.1.1.2 specify that multiple presence factors shall not be used with the approximate load assignment methods other than static moment or lever arm methods because these factors are already incorporated in the distribution factors.

Bridges not meeting the requirements of this Article shall be analyzed as specified in Article 4.6.3.

The distribution of live load, specified in Articles 4.6.2.2.2 and 4.6.2.2.3, may be used for girders, beams, and stringers, other than multiple steel box beams with concrete decks that meet the following conditions and any other conditions identified in tables of distribution factors as specified herein:

- Width of deck is constant;
- Unless otherwise specified, the number of beams is not less than four;

C4.6.2.2.1

The V-load method is one example of a method of curved bridge analysis which starts with straight girder distribution factors (United States Steel, 1984).

The lever rule involves summing moments about one support to find the reaction at another support by assuming that the supported component is hinged at interior supports.

When using the lever rule on a three-girder bridge, the notional model should be taken as shown in Figure C4.6.2.2.1-1. Moments should be taken about the assumed, or notional, hinge in the deck over the middle girder to find the reaction on the exterior girder.

Figure C4.6.2.2.1-1—Notional Model for Applying Lever Rule to Three-Girder Bridges

Provisions in Articles 4.6.2.2.2 and 4.6.2.2.3 that do not appear in earlier editions of the Standard Specifications come primarily from Zokaie et al. (1991). Correction factors for continuity have been deleted for two reasons:

- Correction factors dealing with five percent adjustments were thought to imply misleading levels of accuracy in an approximate method, and
- Analyses of many continuous beam-slab-type bridges indicate that the distribution coefficients for negative moments exceed those obtained for positive moments by approximately ten percent. On the other hand, it has been observed that stresses at or near an internal bearing are reduced due to the fanning of the reaction force. This reduction is about the same magnitude as the increase in distribution factors, hence the two tend to cancel each other out, and thus are omitted from these Specifications.

- Beams are parallel and have approximately the same stiffness;
- Unless otherwise specified, the roadway part of the overhang, d_e , does not exceed 3.0 ft;
- Curvature in plan is less than the limit specified in Article 4.6.1.2.4, or where distribution factors are required in order to implement an acceptable approximate or refined analysis method satisfying the requirements of Article 4.4 for bridges of any degree of curvature in plan; and
- Cross-section is consistent with one of the cross-sections shown in Table 4.6.2.2.1-1.

Where moderate deviations from a constant deck width or parallel beams exist, the distribution factor may either be varied at selected locations along the span or else a single distribution factor may be used in conjunction with a suitable value for beam spacing.

Cast-in-place multicell concrete box girder bridge types may be designed as whole-width structures. Such cross-sections shall be designed for the live load distribution factors in Articles 4.6.2.2.2 and 4.6.2.2.3 for interior girders, multiplied by the number of girders, i.e., webs.

Additional requirements for multiple steel box girders with concrete decks shall be as specified in Article 4.6.2.2.2b.

Where bridges meet the conditions specified herein, permanent loads of and on the deck may be distributed uniformly among the beams and/or stringers.

Live load distribution factors specified herein may be used for permit and rating vehicles whose overall width is comparable to the width of the design truck.

The following notation shall apply to tables in Articles 4.6.2.2.2 and 4.6.2.2.3:

A = area of stringer, beam, or girder (in.²)

In Strength Load Combination II, applying a distribution factor procedure to a loading involving a heavy permit load can be overly conservative unless lane-by-lane distribution factors are available. Use of a refined method of analysis will circumvent this situation.

A rational approach may be used to extend the provisions of this Article to bridges with splayed girders. The distribution factor for live load at any point along the span may be calculated by setting the girder spacing in the equations of this Article equal to half the sum of the center-to-center distance between the girder under consideration and the two girders to either side. This will result in a variable distribution factor along the length of the girder. While the variable distribution factor is theoretically correct, it is not compatible with existing line girder computer programs that only allow constant distribution factors. Further simplifications may be used to allow the use of such computer programs. One such simplification involves running the computer program a number of times equal to the number of spans in the bridge. For each run, the girder spacing is set equal to the maximum girder spacing in one span and the results from this run are applied to this span. This approach is guaranteed to result in conservative design. In the past, some jurisdictions applied the latter approach, but used the girder spacing at the two-thirds or three-fourths points of the span; which will also be an acceptable approximation.

Most of the equations for distribution factors were derived for constant deck width and parallel beams. Past designs with moderate exceptions to these two assumptions have performed well when the S/D distribution factors were used. While the distribution factors specified herein are more representative of actual bridge behavior, common sense indicates that some exceptions are still possible, especially if the parameter S is chosen with prudent judgment, or if the factors are appropriately varied at selected locations along the span.

Whole-width design is appropriate for torsionally stiff cross-sections where load-sharing between girders is extremely high and torsional loads are hard to estimate. Prestressing force should be evenly distributed between girders. Cell width-to-height ratios should be approximately 2:1.

In lieu of more refined information, the St. Venant torsional inertia, J , may be determined as:

- For thin-walled open beam:

$$J = \frac{1}{3} \sum b t^3 \quad (\text{C4.6.2.2.1-1})$$

- For stocky open sections, e.g., prestressed I-beams and T-beams, and solid sections:

$$J = \frac{A^4}{40.0I_p} \quad (\text{C4.6.2.2.1-2})$$

b	=	width of beam (in.)
C	=	stiffness parameter
D	=	width of distribution per lane (ft)
d	=	depth of beam or stringer (in.)
d_e	=	horizontal distance from the centerline of the exterior web of exterior beam at deck level to the interior edge of curb or traffic barrier (ft)
e	=	correction factor
g	=	live load distribution factor representing the number of design lanes
I_p	=	polar moment of inertia (in. ⁴)
J	=	St. Venant torsional inertia (in. ⁴)
k	=	factor used in calculation of distribution factor for girder system bridges
K	=	constant for different types of construction
K_g	=	longitudinal stiffness parameter (in. ⁴)
L	=	span length of beam (ft)
N_b	=	number of beams, stringers, or girders
N_c	=	number of cells in a concrete box girder
N_L	=	number of design lanes, as specified in Article 3.6.1.1.1
S	=	spacing of beams or webs (ft)
t_g	=	depth of steel grid or corrugated steel plank including integral concrete overlay or structural concrete component, less a provision for grinding, grooving, or wear (in.)
t_o	=	depth of structural overlay (in.)
t_s	=	depth of concrete slab (in.)
W	=	edge-to-edge width of bridge (ft)
W_e	=	half the web spacing, plus the total overhang (ft)
θ	=	skew angle (degrees)
μ	=	Poisson's ratio

Unless otherwise stated, the stiffness parameters for area, moments of inertia, and torsional stiffness used herein and in Articles 4.6.2.2.2 and 4.6.2.2.3 shall be taken as those of the cross-section to which traffic will be applied, i.e., usually the composite section.

The term L (length) shall be determined for use in the live load distribution factor equations given in Articles 4.6.2.2.2 and 4.6.2.2.3 as shown in Table 4.6.2.2.1-2.

- For closed thin-walled shapes:

$$J = \frac{4A_o^2}{\sum \frac{s}{t}} \quad (\text{C4.6.2.2.1-3})$$

where:

b	=	width of plate element (in.)
t	=	thickness of plate-like element (in.)
A	=	area of cross-section (in. ²)
I_p	=	polar moment of inertia (in. ⁴)
A_o	=	area enclosed by centerlines of elements (in. ²)
s	=	length of a side element (in.)

Eq. C4.6.2.2.1-2 has been shown to substantially underestimate the torsional stiffness of some concrete I-beams and a more accurate, but more complex, approximation can be found in Eby et al. (1973).

The transverse post-tensioning shown for some cross-sections herein is intended to make the units act together. A minimum 0.25 ksi prestress is recommended.

For beams with variable moment of inertia, K_g may be based on average properties.

For superstructures using bridge type (b) in Table 4.6.2.2.1-1 consisting of simple span precast concrete spread slab beams with precast stay-in-place forms and a cast-in-place concrete slab, live load distribution factors provided in Articles 4.6.2.2.2 and 4.6.2.2.3 may yield results that do not represent in-service behavior. In lieu of a detailed analysis of shear and moment live load distribution factors for this superstructure type, refer to Report Number FHWA/TX-15/0-6722-1, April 2015. Load distribution factors are only valid for a superstructure that is within the specified applicable range listed in the technical report.

For bridge types (f), (g), (h), (i), and (j), longitudinal joints between precast units of the cross-section are shown in Table 4.6.2.2.1-1. This type of construction acts as a monolithic unit if sufficiently interconnected. In Article 5.12.2.3.3f, a fully interconnected joint is identified as a flexural shear joint. This type of interconnection is enhanced by either transverse post-tensioning of an intensity specified above or by a reinforced structural overlay, which is also specified in Article 5.12.2.3.3f, or both. The use of transverse mild steel rods secured by nuts or similar unstressed dowels should not be considered sufficient to achieve full transverse flexural continuity unless demonstrated by testing or experience. Generally, post-tensioning is thought to be more effective than a structural overlay if the intensity specified above is achieved.

In some cases, the lower limit of deck slab thickness, t_s , shown in the range of applicability column in the tables in Articles 4.6.2.2.2 and 4.6.2.2.3, is less than 7.0 in. The research used to develop the equations in those tables reflects the range of slab thickness

shown. Article 9.7.1.1 indicates that concrete decks less than 7.0 in. in thickness should not be used unless approved by the Owner. Lesser values shown in tables in Articles 4.6.2.2.2 and 4.6.2.2.3 are not intended to override Article 9.7.1.1.

The load distribution factor equations for bridge type (d), cast-in-place multicell concrete box girders, were derived by first positioning the vehicle longitudinally and then transversely using an I-section of the box. While it would be more appropriate to develop an algorithm to find the peak of an influence surface, using the present factor for the interior girders multiplied by the number of girders is conservative in most cases.

The value of L to be used for positive and negative moment distribution factors will differ within spans of continuous-girder bridges as will the distribution factors for positive and negative flexure.

The longitudinal stiffness parameter, K_g , shall be taken as:

$$K_g = n(I + Ae_g^2) \quad (4.6.2.2.1-1)$$

in which:

$$n = \frac{E_B}{E_D} \quad (4.6.2.2.1-2)$$

where:

- E_B = modulus of elasticity of beam material (ksi)
- E_D = modulus of elasticity of deck material (ksi)
- I = moment of inertia of beam (in.⁴)
- e_g = distance between the centers of gravity of the basic beam and deck (in.)

The parameters A and I in Eq. 4.6.2.2.1-1 shall be taken as those of the noncomposite beam.

The bridge types indicated in tables in Articles 4.6.2.2.2 and 4.6.2.2.3, with reference to Table 4.6.2.2.1-1, may be taken as representative of the type of bridge to which each approximate equation applies.

Except as permitted by Article 2.5.2.7.1, regardless of the method of analysis used, i.e., approximate or refined exterior girders of girder system bridges shall not have less resistance than an interior beam.

In the rare occasion when the continuous-span arrangement is such that an interior span does not have any positive uniform load moment (i.e., no uniform load points of contraflexure), the region of negative moment near the interior supports would be increased to the centerline of the span, and the L used in determining the live load distribution factors would be the average of the two adjacent spans.

Table 4.6.2.2.1-1—Common Deck Superstructures Covered in Articles 4.6.2.2.2 and 4.6.2.2.3

Supporting Components	Type of Deck	Typical Cross-Section
Steel Beam	Cast-in-place concrete slab, precast concrete slab, steel grid, glued/spiked panels, stressed wood	 (a)
Closed Steel or Precast Concrete Boxes	Cast-in-place concrete slab	 (b)
Open Steel or Precast Concrete Boxes	Cast-in-place concrete slab, precast concrete deck slab	 (c)
Cast-in-Place Concrete Multicell Box	Monolithic concrete	 (d)
Cast-in-Place Concrete T-Beam	Monolithic concrete	 (e)
Precast Solid, Voids, or Cellular Concrete Boxes with Shear Keys	Cast-in-place concrete overlay	 (f)
Precast Solid, Voids, or Cellular Concrete Box with Shear Keys and with or without Transverse Post-Tensioning	Integral concrete	 (g)
Precast Concrete Channel Sections with Shear Keys	Cast-in-place concrete overlay	 (h)

Continued on next page

Table 4.6.2.2.1-1 (continued)—Common Deck Superstructures Covered in Articles 4.6.2.2.2 and 4.6.2.2.3

Supporting Components	Type of Deck	Typical Cross-Section
Precast Concrete Double T-Section with Shear Keys and with or without Transverse Post-Tensioning	Integral concrete	 (i)
Precast Concrete T-Section with Shear Keys and with or without Transverse Post-Tensioning	Integral concrete	 (j)
Precast Concrete I- or Bulb-T-Sections	Cast-in-place concrete, precast concrete	 (k)
Wood Beams	Cast-in-place concrete or plank, glued/spiked panels or stressed wood	 (l)

Table 4.6.2.2.1-2— L for Use in Live Load Distribution Factor Equations

Force Effect	L (ft)
Positive Moment	The length of the span for which moment is being calculated
Negative Moment—Near interior supports of continuous spans from point of contraflexure to point of contraflexure under a uniform load on all spans	The average length of the two adjacent spans
Negative Moment—Other than near interior supports of continuous spans	The length of the span for which moment is being calculated
Shear	The length of the span for which shear is being calculated
Exterior Reaction	The length of the exterior span
Interior Reaction of Continuous Span	The average length of the two adjacent spans

For cast-in-place concrete multicell box shown as cross-section type (d) in Table 4.6.2.2.1-1, the distribution factors in Article 4.6.2.2.2 and 4.6.2.2.3 shall be taken to apply to a notional shape consisting of a web, overhangs of an exterior web, and the associated half flanges between a web under consideration and the next adjacent web or webs.

With the Owner's concurrence, the simplifications provided in Table 4.6.2.2.1-3 may be used:

Table 4.6.2.2.1-3—Constant Values for Articles 4.6.2.2.2 and 4.6.2.2.3

Equation Parameters	Table Reference	Simplified Value			
		a	e	k	f,g,i,j
$\left(\frac{K_g}{12.0L_t^3}\right)^{0.1}$	4.6.2.2.2b-1	1.02	1.05	1.09	—

4.6.2.2.2—Distribution Factor Method for Moment and Shear

4.6.2.2.2a—Interior Beams with Wood Decks

The live load flexural moment and shear for interior beams with transverse wood decks may be determined by applying the live load distribution factor, g , specified in Table 4.6.2.2.2a-1 and Eq. 4.6.2.2.2a-1.

When investigation of shear parallel to the grain in wood components is required, the distributed live load shear shall be determined by the following expression:

$$V_{LL} = 0.50[(0.60V_{LU}) + V_{LD}] \quad (4.6.2.2.2a-1)$$

where:

V_{LL} = distributed live load vertical shear (kips)

V_{LU} = maximum vertical shear at $3d$ or $L/4$ due to undistributed wheel loads (kips)

V_{LD} = maximum vertical shear at $3d$ or $L/4$ due to wheel loads distributed laterally as specified herein (kips)

For undistributed wheel loads, one line of wheels is assumed to be carried by one bending member.

Table 4.6.2.2.2a-1—Live Load Distribution Factor for Moment and Shear in Interior Beams with Wood Decks

Type of Deck	Applicable Cross-Section from Table 4.6.2.2.1-1	One Design Lane Loaded	Two or More Design Lanes Loaded	Range of Applicability
Plank	(a), (l)	$S/6.7$	$S/7.5$	$S \leq 5.0$

Glued Laminated Panels on Glued Laminated Stringers	(a), (l)	$S/10.0$	$S/10.0$	$S \leq 6.0$
Glue Laminated Panels on Steel Stringers	(a), (l)	$S/8.8$	$S/9.0$	$S \leq 6.0$

4.6.2.2.2b—Interior Beams with Concrete Decks

C4.6.2.2.2b

The live load flexural moment for interior beams with concrete decks may be determined by applying the live load distribution factor, g , specified in Table 4.6.2.2.2b-1.

For the concrete beams, other than box beams, used in multibeam decks with shear keys:

- Deep, rigid end diaphragms shall be provided to ensure proper load distribution; and
- If the stem spacing of stemmed beams is less than 4.0 ft or more than 10.0 ft, a refined analysis complying with Article 4.6.3 shall be used.

For multiple steel box girders with a concrete deck in bridges satisfying the requirements of Article 6.11.2.3, the live load flexural moment may be determined using the appropriate distribution factor specified in Table 4.6.2.2.2b-1.

Where the spacing of the box girders varies along the length of the bridge, the distribution factor may either be varied at selected locations along the span or else a single distribution factor may be used in conjunction with a suitable value of N_L . In either case, the value of N_L shall be determined as specified in Article 3.6.1.1.1, using the width, w , taken at the section under consideration.

The results of analytical and model studies of simple span multiple box-section bridges, reported in Johnston and Mattock (1967), showed that folded plate theory could be used to analyze the behavior of bridges of this type. The folded plate theory was used to obtain the maximum load per girder, produced by various critical combinations of loading on 31 bridges having various spans, numbers of box girders, and numbers of traffic lanes.

Multiple presence factors, specified in Table 3.6.1.1.2-1, are not applied because the multiple factors in past editions of the Standard Specifications were considered in the development of the equation in Table 4.6.2.2.2b-1 for multiple steel box girders.

The lateral load distribution obtained for simple spans is also considered applicable to continuous structures.

The bridges considered in the development of the equations had interior end diaphragms only, i.e., no interior diaphragms within the spans, and no exterior diaphragms anywhere between boxes. If interior or exterior diaphragms are provided within the span, the transverse load distribution characteristics of the bridge will be improved to some degree. This improvement can be evaluated, if desired, using the analysis methods identified in Article 4.4.

Table 4.6.2.2.2b-1—Live Load Distribution Factor for Moment in Interior Beams

Type of Superstructure	Applicable Cross-Section from Table 4.6.2.2.1-1	Distribution Factors	Range of Applicability
Wood Deck on Wood or Steel Beams	(a), (l)	See Table 4.6.2.2.2a-1	
Concrete Deck on Wood Beams	(l)	One Design Lane Loaded: $S/12.0$ Two or More Design Lanes Loaded: $S/10.0$	$S \leq 6.0$

Rectangular beams with circular voids:	0.8														
Channel beams	2.2														
T-beam	2.0														
Double T-beam	2.0														
Open Steel Grid Deck on Steel Beams	(a)	One Design Lane Loaded: $S/7.5$ If $t_g < 4.0$ $S/10.0$ If $t_g \geq 4.0$ Two or More Design Lanes Loaded: $S/8.0$ If $t_g < 4.0$ $S/10.0$ If $t_g \geq 4.0$	$S \leq 6.0$ $S \leq 10.5$												
Concrete Deck on Multiple Steel Box Girders	(b), (c)	Regardless of Number of Loaded Lanes: $0.05 + 0.85 \frac{N_L}{N_b} + \frac{0.425}{N_L}$	$0.5 \leq \frac{N_L}{N_b} \leq 1.5$												

4.6.2.2.2c—Interior Beams with Corrugated Steel Decks

The live load flexural moment for interior beams with corrugated steel plank deck may be determined by applying the live load distribution factor, g , specified in Table 4.6.2.2.2c-1.

Table 4.6.2.2.2c-1—Live Load Distribution Factor for Moment in Interior Beams with Corrugated Steel Plank Decks

One Design Lane Loaded	Two or More Design Lanes Loaded	Range of Applicability
$S/9.2$	$S/9.0$	$S \leq 5.5$ $t_g \geq 2.0$

4.6.2.2.2d—Exterior Beams

The live load flexural moment for exterior beams may be determined by applying the live load distribution factor, g , specified in Table 4.6.2.2.2d-1. However, if the girders are not equally spaced and g for the exterior girder is a function of g_{interior} , g_{interior} should be based on the spacing between the exterior and first-interior girder.

The distance, d_e , shall be taken as positive if the exterior web is inboard of the interior face of the traffic railing and negative if it is outboard of the curb or traffic barrier. However, if a negative value for d_e falls outside the range of applicability as shown in Table 4.6.2.2.2.d-1 d_e should be limited to -1.0 .

In steel beam-slab bridge cross-sections with diaphragms or cross-frames, the distribution factor for the exterior beam shall not be taken to be less than that which would be obtained by assuming that the cross-section deflects and rotates as a rigid cross-section. The provisions of Article 3.6.1.1.2 shall apply.

C4.6.2.2.2d

The distribution factor for girders in a multigirder cross-section, types (a), (e), and (k) in Table 4.6.2.2.1-1, was determined without consideration of diaphragm or cross-frames, or parapets. Some research shows a minimal contribution to load transfer from diaphragms or cross-bracing and resultant increase in force effects in external girders. However, reactions may be calculated using a procedure similar to the conventional approximation for loads on piles as shown below.

$$R = \frac{N_L}{N_b} + \frac{X_{\text{ext}} \sum_{e=1}^{N_L} e}{\sum_{b=1}^{N_b} x^2} \quad (\text{C4.6.2.2.2d-1})$$

where:

- R = reaction on exterior beam in terms of lanes
- N_L = number of loaded lanes under consideration
- e = eccentricity of a design truck or a design lane load from the center of gravity of the pattern of girders (ft)
- x = horizontal distance from the center of gravity of the pattern of girders to each girder (ft)
- X_{ext} = horizontal distance from the center of gravity of the pattern of girders to the exterior girder (ft)
- N_b = number of beams or girders

Table 4.6.2.2d-1—Live Load Distribution Factor for Moment in Exterior Longitudinal Beams

4.6.2.2.2e—Skewed Bridges

When the line supports are skewed and the difference between skew angles of two adjacent lines of supports does not exceed 10 degrees, the bending moment in the beams may be reduced in accordance with Table 4.6.2.2.2e-1.

C4.6.2.2.2e

Accepted reduction factors are not currently available for cases not covered in Table 4.6.2.2.2e-1.

Table 4.6.2.2.2e-1—Reduction of Live Load Distribution Factors for Moment in Longitudinal Beams on Skewed Supports

Type of Superstructure	Applicable Cross-Section from Table 4.6.2.2.1-1	Any Number of Design Lanes Loaded	Range of Applicability
Concrete Deck or Filled Grid, Partially Filled Grid, or Unfilled Grid Deck Composite with Reinforced Concrete Slab on Steel or Concrete Beams; Concrete T-Beams, T- and Double T-Sections	(a), (e), and (k); also (i) and (j) if sufficiently connected to act as a unit	$1 - c_1 (\tan \theta)^{1.5}$ $c_1 = 0.25 \left(\frac{K_g}{12.0 L t_s^3} \right)^{0.25} \left(\frac{S}{L} \right)^{0.5}$ If $\theta < 30^\circ$ then $c_1 = 0.0$ If $\theta > 60^\circ$ use $\theta = 60^\circ$	$30^\circ \leq \theta \leq 60^\circ$ $3.5 \leq S \leq 16.0$ $20 \leq L \leq 240$ $N_b \geq 4$
Concrete Deck on Concrete Spread Box Beams, Cast-in-Place Multicell Box, Concrete Beams Used in Multibeam Decks	(b), (c), (d), (f), (g), (h); also (i) and (j) if sufficiently connected to prevent vertical displacement at the interface	$1.05 - 0.25 \tan \theta \leq 1.0$ If $\theta > 60^\circ$ use $\theta = 60^\circ$	$0^\circ \leq \theta \leq 60^\circ$

4.6.2.2.2f—Flexural Moments and Shear in Transverse Floorbeams

If the deck is supported directly by transverse floorbeams, the floorbeams may be designed for loads determined in accordance with Table 4.6.2.2.2f-1.

The live load distribution factor, g , provided in Table 4.6.2.2.2f-1 shall be used in conjunction with the 32.0-kip design axle load alone. For spacings of floorbeams outside the given ranges of applicability, all of the design live loads shall be considered, and the lever rule may be used.

Table 4.6.2.2.2f-1—Live Load Distribution Factor for Transverse Beams for Moment and Shear

Type of Deck	Live Load Distribution Factors for Each Floorbeam	Range of Applicability
Plank	$\frac{S}{4}$	N/A
Laminated Wood Deck	$\frac{S}{5}$	$S \leq 5.0$
Concrete	$\frac{S}{6}$	$S \leq 6.0$
Steel Grid and Unfilled Grid Deck Composite with Reinforced Concrete Slab	$\frac{S}{4.5}$	$t_g \leq 4.0$ $S \leq 5.0$
Steel Grid and Unfilled Grid Deck Composite with Reinforced Concrete Slab	$\frac{S}{6}$	$t_g > 4.0$ $S \leq 6.0$
Steel Bridge Corrugated Plank	$\frac{S}{5.5}$	$t_g \geq 2.0$

4.6.2.2.3—Distribution Factor Method for Shear

4.6.2.2.3a—Interior Beams

The live load shear for interior beams may be determined by applying the live load distribution factor, g , specified in Table 4.6.2.2.3a-1. For interior beam types not listed in Table 4.6.2.2.3a-1, lateral distribution of the wheel or axle adjacent to the end of span shall be that produced by use of the lever rule.

For concrete box beams used in multibeam decks, if the values of I or J do not comply with the limitations in Table 4.6.2.2.3a-1, the distribution factor for shear may be taken as that for moment.

Table 4.6.2.2.3a-1—Live Load Distribution Factor for Shear in Interior Beams

4.6.2.2.3b—Exterior Beams

The live load shear for exterior beams may be determined by applying the live load distribution factor, g , specified in Table 4.6.2.2.3b-1. For cases not addressed in Table 4.6.2.2.3a-1 and Table 4.6.2.2.3b-1, the live load distribution to exterior beams shall be determined by using the lever rule.

The parameter d_e shall be taken as positive if the exterior web is inboard of the curb or traffic barrier and negative if it is outboard.

The additional provisions for exterior beams in beam-slab bridges with cross-frames or diaphragms, specified in Article 4.6.2.2d, shall apply.

Table 4.6.2.2.3b-1—Live Load Distribution Factor for Shear in Exterior Beams

4.6.2.2.3c—Skewed Bridges

Shear in bridge girders shall be adjusted when the line of support is skewed. The value of the correction factor shall be obtained from Table 4.6.2.2.3c-1 and applied to the live load distribution factors, g , specified in Table 4.6.2.2.3b-1 for exterior beams at the obtuse corner of the span, and in Table 4.6.2.2.3a-1 for interior beams. If the beams are well connected and behave as a unit, only the exterior and first interior beam need to be adjusted. The shear correction factors should be applied between the point of support at the obtuse corner and mid-span, and may be decreased linearly to a value of 1.0 at mid-span, regardless of end condition. This factor should not be applied in addition to modeling skewed supports.

In determining the end shear in deck system bridges, the skew correction at the obtuse corner shall be applied to all the beams.

C4.6.2.2.3c

Verifiable correction factors are not available for cases not covered in Table 4.6.2.2.3c-1, including large skews and skews in combination with curved bridge alignments. When torsional force effects due to skew become significant, load distribution factors are inappropriate.

The equal treatment of all beams in a multibeam bridge (box beams and deck girders) is conservative regarding positive reaction and shear. The contribution from transverse post-tensioning is conservatively ignored. However, it is not necessarily conservative regarding uplift in the case of large skew and short exterior spans of continuous beams. A supplementary investigation of uplift should be considered using the correction factor from Table 4.6.2.2.3c-1, i.e., the terms other than 1.0, taken as negative for the exterior beam on the acute corner.

Table 4.6.2.2.3c-1—Correction Factors for Live Load Distribution Factors for Support Shear of the Obtuse Corner

Type of Superstructure	Applicable Cross-Section from Table 4.6.2.2.1-1	Correction Factor	Range of Applicability
Concrete Deck or Filled Grid, Partially Filled Grid, or Unfilled Grid Deck Composite with Reinforced Concrete Slab on Steel or Concrete Beams; Concrete T-Beams, T- and Double T-Sections	(a), (e), (k); also (i) and (j) if sufficiently connected to act as a unit	$1.0 + 0.20 \left(\frac{12.0 L t_s^3}{K_g} \right)^{0.3} \tan \theta$	$0^\circ \leq \theta \leq 60^\circ$ $3.5 \leq S \leq 16.0$ $20 \leq L \leq 240$ $N_b \geq 4$
Cast-in-Place Concrete Multicell Box	(d)	For exterior girder: $1.0 + \left(0.25 + \frac{12.0 L}{70 d} \right) \tan \theta$ For first interior girder: $1.0 + \left(0.042 + \frac{12.0 L}{420 d} \right) \tan \theta$	$0^\circ < \theta \leq 60^\circ$ $6.0 < S \leq 13.0$ $20 \leq L \leq 240$ $35 \leq d \leq 110$ $N_e \geq 3$
Concrete Deck on Spread Concrete Box Beams	(b), (c)	$1.0 + \frac{\sqrt{L d}}{6 S} \tan \theta$	$0^\circ < \theta \leq 60^\circ$ $6.0 \leq S \leq 11.5$ $20 \leq L \leq 140$ $18 \leq d \leq 65$ $N_b \geq 3$
Concrete Box Beams Used in Multibeam Decks	(f), (g)	$1.0 + \frac{12.0 L}{90 d} \sqrt{\tan \theta}$	$0^\circ < \theta \leq 60^\circ$ $20 \leq L \leq 120$ $17 \leq d \leq 60$ $35 \leq b \leq 60$ $5 \leq N_b \leq 20$

4.6.2.2.4—Curved Steel Bridges

Approximate analysis methods may be used for analysis of curved steel bridges. The Engineer shall ascertain that the approximate analysis method used is appropriate by confirming that the method satisfies the requirements stated in Article 4.4.

In curved systems, consideration should be given to placing parapets, sidewalks, barriers, and other heavy line loads at their actual location on the bridge. Wearing surface and other distributed loads may be assumed to be uniformly distributed to each girder in the cross-section.

C4.6.2.2.4

The V-load method (United States Steel, 1984) has been a widely used approximate method for analyzing horizontally curved steel I-girder bridges. The method assumes that the internal torsional load on the bridge—resulting solely from the curvature—is resisted by self-equilibrating sets of shears between adjacent girders. The V-load method does not directly account for sources of torque other than curvature and the method does not account for the horizontal shear stiffness of the concrete deck. The method is only valid for loads such as normal highway loadings. For exceptional loadings, a more refined analysis is required. The method assumes a linear distribution of girder shears across the bridge section; thus, the girders at a given cross-section should have approximately the same vertical stiffness. The V-load method is also not directly applicable to structures with reverse curvature or to a closed-framed system with horizontal lateral bracing near, or in the plane of one or both flanges. The V-load method does not directly account for girder twist; thus, lateral deflections, which become important on bridges with large spans and/or sharp skews and vertical deflections, may be significantly underestimated. In certain situations, the V-load method may not detect uplift at end bearings. The method is best suited for preliminary design, but may also be suitable for final design of structures with radial supports or supports skewed less than approximately 10 degrees.

The M/R method provides a means to account for the effect of curvature in curved box girder bridges. The method and suggested limitations on its use are discussed by Tung and Fountain (1970).

Vertical reactions at interior supports on the concave side of continuous-span bridges may be significantly underestimated by both the V-load and M/R methods.

Live load distribution factors for use with the V-load and M/R methods may be determined using the appropriate provisions of Article 4.6.2.2.

Strict rules and limitations on the applicability of both of these approximate methods do not exist. The Engineer must determine when approximate methods of analysis are appropriate.

4.6.2.2.5—Special Loads with Other Traffic

Except as specified herein, the provisions of this Article may be applied where the approximate methods of analysis for the analysis of beam-slab bridges specified in Article 4.6.2.2 and slab-type bridges specified in Article 4.6.2.3 are used. The provisions of this Article shall not be applied where either:

- The lever rule has been specified for both single-lane and multiple-lane loadings; or
- The special requirement for exterior girders of beam-slab bridge cross-sections

C4.6.2.2.5

Because the number of loaded lanes used to determine the multiple-lane live load distribution factor, g_m , is not known, the multiple-lane multiple presence factor, m , is implicitly set equal to 1.0 in this equation, which assumes only two lanes are loaded, resulting in a conservative final force effect over using the multiple presence factors for three or more lanes loaded.

The factor Z is used to distinguish between situations where the single-lane live load distribution factor was determined from a specified algebraic equation and situations where the lever rule was specified for the determination of the single-lane live

with diaphragms specified in Article 4.6.2.2.2d has been utilized for simplified analysis.

Force effects resulting from heavy vehicles in one lane with routine traffic in adjacent lanes, such as might be considered with Load Combination Strength II in Table 3.4.1-1, may be determined as:

$$G = G_p \left(\frac{g_l}{Z} \right) + G_D \left(g_m - \frac{g_l}{Z} \right) \quad (4.6.2.2.5-1)$$

where:

G	=	final force effect applied to a girder (kip or kip-ft)
G_p	=	force effect due to overload truck (kip or kip-ft)
g_1	=	single-lane live load distribution factor
G_D	=	force effect due to design loads (kip or kip-ft)
g_m	=	multiple-lane live load distribution factor
Z	=	a factor taken as 1.20 where the lever rule was not utilized, and 1.0 where the lever rule was used for a single-lane live load distribution factor

load distribution factor. In the situation where an algebraic equation was specified, the multiple presence factor of 1.20 for a single lane loaded has been included in the algebraic equation and must be removed by using $Z = 1.20$ in Eq. 4.6.2.2.5-1 so that the distribution factor can be utilized in Eq. 4.6.2.2.5-1 to determine the force effect resulting from a multiple-lane loading.

This formula was developed from a similar formula presented without investigation by Modjeski and Masters, Inc. (1994) in a report to the Pennsylvania Department of Transportation in 1994, as was examined in Zokaie (1998).

4.6.2.3—Equivalent Strip Widths for Slab-Type Bridges

C4.6.2.3

This Article shall be applied to the types of cross-sections shown schematically in Table 4.6.2.3-1. For the purpose of this Article, cast-in-place voided slab bridges may be considered as slab bridges.

The equivalent width of longitudinal strips per lane for both shear and moment with one lane, i.e., two lines of wheels, loaded may be determined as:

$$E = 10.0 + 5.0\sqrt{L_j W_j} \quad (4.6.2.3-1)$$

The equivalent width of longitudinal strips per lane for both shear and moment with more than one lane loaded may be determined as:

$$E = 84.0 + 1.44\sqrt{L_f W_f} \leq \frac{12.0W}{N_f} \quad (4.6.2.3-2)$$

where:

E = equivalent width (in.)
 L_1 = modified span length taken equal to the lesser of the actual span or 60.0 (ft)
 W_1 = modified edge-to-edge width of bridge taken to be equal to the lesser of the actual width or 60.0 for multilane loading, or 30.0 for single-lane loading (ft)
 W = physical edge-to-edge width of bridge (ft)
 N_L = number of design lanes as specified in Article 3.6.1.1.1

In Eq. 4.6.2.3-1, the strip width has been divided by 1.20 to account for the multiple presence effect.

For skewed bridges, the longitudinal force effects may be reduced by the factor, r :

$$r = 1.05 - 0.25 \tan \theta \leq 1.00$$

(4.6.2.3-3)

where:

θ = skew angle (degrees)

Table 4.6.2.3-1—Typical Schematic Cross-Section

Supporting Components	Type of Deck	Typical Cross-Section
Cast-in-Place Concrete Slab or Voided Slab	Monolithic	 (a)
Stressed Wood Deck	Integral Wood	 (b)
Glued/Spiked Wood Panels with Spreader Beam	Integral Wood	 (c)

4.6.2.4—Truss and Arch Bridges

The lever rule may be used for the distribution of gravity loads in trusses and arches when analyzed as planar structures. If a space analysis is used, either the lever rule or direct loading through the deck or deck system may be used.

Where loads, other than the self-weight of the members and wind loads thereon, are transmitted to the truss at the panel points, the truss may be analyzed as a pin-connected assembly.

4.6.2.5—Effective Length Factor, K

Physical column lengths shall be multiplied by an effective length factor, K , to compensate for rotational and translational boundary conditions other than pinned ends.

In the absence of a more refined analysis, where lateral stability is provided by diagonal bracing or other suitable means, the effective length factor in the braced plane, K , for the compression members in triangulated trusses, trusses, and frames may be taken as:

- For bolted or welded end connections at both ends: $K = 0.750$
- For pinned connections at both ends: $K = 0.875$
- For single angles, regardless of end connection: $K = 1.0$

C4.6.2.5

Equations for the compressive resistance of columns and moment magnification factors for beam columns include a factor, K , which is used to modify the length according to the restraint at the ends of the column against rotation and translation.

K is the ratio of the effective length of an idealized pin-end column to the actual length of a column with various other end conditions. KL represents the length between inflection points of a buckled column influenced by the restraint against rotation and translation of column ends. Theoretical values of K , as provided by the Structural Stability Research Council, are given in Table C4.6.2.5-1 for some idealized column end conditions.

Vierendeel trusses shall be treated as unbraced frames.

Table C4.6.2.5-1—Effective Length Factors, K

Buckled shape of column is shown by dashed line	(a) 	(b) 	(c) 	(d) 	(e) 	(f) 
Theoretical K value	0.5	0.7	1.0	1.0	2.0	2.0
Design value of K when ideal conditions are approximated	0.65	0.80	1.0	1.2	2.1	2.0
End condition code	   	Rotation fixed Rotation free Rotation fixed Rotation free	Translation fixed Translation fixed Translation free Translation free			

Because actual column end conditions seldom comply fully with idealized restraint conditions against rotation and translation, the design values suggested by the Structural Stability Research Council are higher than the idealized values.

Lateral stability of columns in continuous frames, unbraced by attachment to shear walls, diagonal bracing, or adjacent structures, depends on the flexural stiffness of the rigidly connected beams. Therefore, the effective length factor, K , is a function of the total flexural restraint provided by the beams at the ends of the column. If the stiffness of the beams is small in relation to that of the column, the value of K could exceed 2.0.

Single angles are loaded through one leg and are subject to eccentricity and twist, which is often not recognized. K is set equal to 1.0 for these members to more closely match the strength provided in the Guide for Design of Steel Transmission Towers (ASCE Manual No. 52, 1971).

Assuming that only elastic action occurs and that all columns buckle simultaneously, it can be shown that (Chen and Liu, 1991) (ASCE Task Committee on Effective Length, 1997):

For braced frames:

$$\frac{G_a G_b \left(\frac{\pi}{K} \right)^2}{4} + \frac{G_a + G_b}{2} \left(1 - \frac{\frac{\pi}{K}}{\tan \left(\frac{\pi}{K} \right)} \right) + \frac{2 \tan \left(\frac{\pi}{2K} \right)}{\frac{\pi}{K}} = 1$$

(C4.6.2.5-1)

For unbraced frames:

$$\frac{G_a G_b \left(\frac{\pi}{K} \right)^2 - 36}{6 (G_a + G_b)} = \frac{\frac{\pi}{K}}{\tan \left(\frac{\pi}{K} \right)} \quad (\text{C4.6.2.5-2})$$

where subscripts a and b refer to the two ends of the column under consideration

in which:

$$G = \frac{\Sigma \left(\frac{E_c I_c}{L_c} \right)}{\Sigma \left(\frac{E_g I_g}{L_g} \right)} \quad (\text{C4.6.2.5-3})$$

where:

- Σ = summation of the properties of components rigidly connected to an end of the column in the plane of flexure
- E_c = modulus of elasticity of column (ksi)
- I_c = moment of inertia of column (in.⁴)
- L_c = unbraced length of column (in.)
- E_g = modulus of elasticity of beam or other restraining member (ksi)
- I_g = moment of inertia of beam or other restraining member (in.⁴)
- L_g = unsupported length of beam or other restraining member (in.)
- K = effective length factor for the column under consideration

Figures C4.6.2.5-1 and C4.6.2.5-2 are graphical representations of the relationship among K , G_a , and G_b for Eqs. C4.6.2.5-1 and C4.6.2.5-2, respectively. The figures can be used to obtain values of K directly.

Eqs. C4.6.2.5-1, C4.6.2.5-2, and the alignment charts in Figures C4.6.2.5-1 and C4.6.2.5-2 are based on assumptions of idealized conditions. The development of the chart and formula can be found in textbooks such as Salmon and Johnson (1990) and Chen and Lui (1991). When actual conditions differ significantly from these idealized assumptions, unrealistic designs may result. Galambos (1988), Yura (1971), Disque (1973), Duan and Chen (1988), and AISC (1993) may be used to evaluate end conditions more accurately.

Figure C4.6.2.5-1—Alignment Chart for Determining Effective Length Factor, K , for Braced Frames

Figure C4.6.2.5-2—Alignment Chart for Determining Effective Length Factor, K , for Unbraced Frames

The following applies to the use of Figures C4.6.2.5-1 and C4.6.2.5-2:

- For column ends supported by but not rigidly connected to a footing or foundation, G is theoretically equal to infinity, but unless actually designed as a true frictionless pin, may be taken equal to 10 for practical design. If the column end is rigidly attached to a properly designed footing, G may be taken equal to 1.0. Smaller values may be taken if justified by analysis.
- In computing effective length factors for members with monolithic connections, it is important to properly evaluate the degree of fixity in the foundation using engineering judgment. In absence of a more refined analysis, the following values can be used:

Condition	G
Footing anchored on rock	1.5
Footing not anchored on rock	3.0
Footing on soil	5.0
Footing on multiple rows of end bearing piles	1.0

In lieu of the alignment charts, the following alternative K -factor equations (Duan, King, and Chen, 1993) may be used.

For braced frames:

$$K = 1 - \frac{1}{5 + 9G_a} - \frac{1}{5 + 9G_b} - \frac{1}{10 + G_a G_b} \quad (\text{C4.6.2.5-4})$$

For unbraced frames:

- For $K < 2$

$$K = 4 - \frac{1}{1 + 0.2G_a} - \frac{1}{1 + 0.2G_b} - \frac{1}{1 + 0.01G_a G_b} \quad (\text{C4.6.2.5-5})$$

- For $K \geq 2$

$$K = \frac{2\pi a}{0.9 + \sqrt{0.81 + 4ab}} \quad (\text{C4.6.2.5-6})$$

in which:

$$a = \frac{G_a G_b}{G_a + G_b} + 3 \quad (\text{C4.6.2.5-7})$$

$$b = \frac{36}{G_a + G_b} + 6 \quad (\text{C4.6.2.5-8})$$

Eq. C4.6.2.5-5 is used first. If the value of K calculated by Eq. C4.6.2.5-5 is greater than 2, Eq. C4.6.2.5-6 is used. The values for K calculated using Eqs. C4.6.2.5-5 and C4.6.2.5-6 are a good fit with results from the alignment chart Eqs. C4.6.2.5-1, C4.6.2.5-2, C4.6.2.5-3, and allow an Engineer to perform a direct noniterative solution for K .

4.6.2.6—Effective Flange Width

4.6.2.6.1—General

Unless specified otherwise in this Article or in Articles 4.6.2.6.2, 4.6.2.6.3, or 4.6.2.6.5, the effective flange width of a concrete deck slab in composite or monolithic construction may be taken as the tributary width perpendicular to the axis of the member for determining cross-section stiffnesses for analysis and for determining flexural resistances. The effective flange width of orthotropic steel decks shall be as specified in Article 4.6.2.6.4. For the calculation of live load deflections, where required, the provisions of Article 2.5.2.6.2 shall apply.

Where a structurally continuous concrete barrier is present and is included in the structural analysis as permitted in Article 4.5.1, the deck slab overhang width used for the analysis as well as for checking the composite girder resistance may be extended by:

$$\Delta w = \frac{A_b}{2t_s} \quad (4.6.2.6.1-1)$$

where:

A_b = cross-sectional area of the barrier (in.²)
 t_s = thickness of deck slab (in.)

The slab effective flange width in composite girder and/or stringer systems or in the chords of composite deck trusses may be taken as one-half the distance to the adjacent stringer or girder on each side of the component, or one-half the distance to the adjacent stringer or girder plus the full overhang width. Otherwise, the slab effective flange width should be determined by a refined analysis when:

- the composite or monolithic member cross-section is subjected to significant combined axial force and bending, with the exception that forces induced by restraint of thermal expansion may be determined in beam-slab systems using the slab tributary width;

C4.6.2.6.1

Longitudinal stresses are distributed across the deck of composite and monolithic flexural members by in-plane shear stresses. Due to the corresponding shear deformations, plane sections do not remain plane and the longitudinal stresses across the deck are not uniform. This phenomenon is referred to as shear lag. The effective flange width is the width of the deck over which the assumed uniformly distributed longitudinal stresses result in approximately the same deck force and member moments calculated from elementary beam theory assuming plane sections remain plane, as are produced by the nonuniform stress distribution.

The provisions of this Article apply to all longitudinal flexural members composite or monolithic with a deck slab, including girders and stringers. They are based on finite element studies of various bridge types and configurations, corroborated by experimental tests and sensitivity analysis of various candidate regression equations (Chen et al., 2005). Chen et al. (2005) found that bridges with larger L/S (ratio of span length to girder spacing) consistently exhibited an effective width, b_e , equal to the tributary width, b . Nonskewed bridges with $L/S = 3.1$, the smallest value of L/S considered in the Chen et al. (2005) study, exhibited $b_e = b$ in the maximum positive bending regions and approximately $b_e = 0.9b$ in the maximum negative bending regions under service limit state conditions. However, they exhibited $b_e = b$ in these regions in all cases at the strength limit state. Bridges with large skew angles often exhibited $b_e < b$ in both the maximum positive and negative moment regions, particularly in cases with small L/S . However, when various potential provisions were assessed using the Rating Factor, RF , as a measure of impact, the influence of using full width ($b_e = b$) was found to be minimal. Therefore, the use of the tributary width is justified in all cases within the limits specified in this Article. Chen et al. (2005) demonstrated that there is no significant relationship between the slab effective width and the slab thickness.

These provisions are considered applicable for skew angles less than or equal to 75 degrees, L/S greater than or equal to 2.0 and overhang widths less than or equal to

- the largest skew angle, θ , in the bridge system is greater than 75 degrees, where θ is the angle of a bearing line measured relative to a normal to the centerline of a longitudinal component;
- the slab spans longitudinally between transverse floorbeams; or
- the slab is designed for two-way action.

0.5S. In unusual cases where these limits are violated, a refined analysis should be used to determine the slab effective width. Furthermore, these provisions are considered applicable for slab-beam bridges with unequal skew angles of the bearing lines, splayed girders, horizontally curved girders, cantilever spans, and various unequal span lengths of continuous spans, although these parameters have not been investigated extensively in studies to date. These recommendations are based on the fact that the participation of the slab in these broader parametric cases is fundamentally similar to the participation of the slab in the specific parametric cases that have been studied.

The use of one-half the distance to the adjacent stringer or girder in calculating the effective width of the main girders in composite girder and/or stringer systems or the truss chords in composite deck trusses is a conservative assumption for the main structural components, since typically a larger width of the slab can be expected to participate with the main girders or truss chords. However, this tributary width assumption may lead to an underestimation of the shear connector requirements and a lack of consideration of axial forces and bending moments in the composite stringers or girders due to the global effects. To utilize a larger slab width for the main girders or truss chords, a refined analysis should be considered.

The specific cases in which a refined analysis is recommended are so listed because they are significantly beyond the conventional application of the concept of a slab effective width. These cases include tied arches where the deck slab is designed to contribute to the resistance of the tie girders and cable-stayed bridges with a composite deck slab. Chen et al. (2005) provides a few case study results for simplified lower-bound slab effective widths in composite deck systems of cable-stayed bridges with certain specific characteristics.

4.6.2.6.2—Segmental Concrete Box Beams and Single-Cell, Cast-in-Place Box Beams

The effective flange width may be assumed equal to the physical flange width if:

- $b \leq 0.1 l_i$
- $b \leq 0.3 d_o$

Otherwise, the effective width of outstanding flanges may be taken as specified in Figures 4.6.2.6.2-1 through 4.6.2.6.2-4, where:

- d_o = depth of superstructure (in.)
 b = physical flange width on each side of the web, e.g., b_1 , b_2 , and b_3 , as shown in Figure 4.6.2.6.2-3 (in.)
 b_e = effective flange width corresponding to the particular position of the section of interest in the span as specified in Figure 4.6.2.6.2-1 (in.)

C4.6.2.6.2

One possible alternative to the procedure specified in this Article is contained in Clause 3-10.2 of the 1991 Ontario Highway Bridge Design Code, which provides an equation for determining the effective flange width for use in calculating flexural resistances and stresses.

Superposition of local two-way slab flexural stresses due to wheel loads and the primary longitudinal flexural stresses is not normally required.

The effective flange widths, b_m and b_s , are determined as the product of the coefficient in Figure 4.6.2.6.2-2 and the physical distance, b , as indicated in Figure 4.6.2.6.2-3.

- b_m = effective flange width for interior portions of a span as determined from Figure 4.6.2.6.2-2; a special case of b_e (in.)
- b_s = effective flange width at interior support or for cantilever arm as determined from Figure 4.6.2.6.2-2; a special case of b_e (in.)
- a = portion of span subject to a transition in effective flange width taken as the lesser of the physical flange width on each side of the web shown in Figure 4.6.2.6.2-3 or one-quarter of the span length (in.)
- ℓ_i = a notional span length specified in Figure 4.6.2.6.2-1 for the purpose of determining effective flange widths using Figure 4.6.2.6.2-2

The following interpretations apply:

- In any event, the effective flange width shall not be taken as greater than the physical width.
- The effects of unsymmetrical loading on the effective flange width may be disregarded.
- The value of b_s shall be determined using the greater of the effective span lengths adjacent to the support.
- If b_m is less than b_s in a span, the pattern of the effective width within the span may be determined by the connecting line of the effective widths, b_s , at adjoining support points.

For the superposition of local and global force effects, the distribution of stresses due to the global force effects may be assumed to have a straight line pattern in accordance with Figure 4.6.2.6.2-3c. The linear stress distribution should be determined from the constant stress distribution using the conditions that the flange force remains unchanged and that the maximum width of the linear stress distribution on each side of a web is 2.0 times the effective flange width.

The section properties for normal forces may be based on the pattern according to Figure 4.6.2.6.2-4 or determined by more rigorous analysis.

If the linear stress distributions intersect a free edge or each other before reaching the maximum width, the linear stress distribution is a trapezoid; otherwise, it is a triangle. This is shown in Figure 4.6.2.6.2-3c.

Figure 4.6.2.6.2-4 is intended only for calculation of resistance due to anchorage of post-tensioning tendons and other concentrated forces and may be disregarded in the general analysis to determine force effects.

System		Pattern of b_m/b
Single-Span Girder $\ell_i = 1.0\ell$		
Continuous Girder	End Span $\ell_i = 0.8\ell$	
	Interior Span $\ell_i = 0.6\ell$	
Cantilever Arm $\ell_i = 1.5\ell$		

Figure 4.6.2.6.2-1—Pattern of Effective Flange Width, b_m , b_s , and b Figure 4.6.2.6.2-2—Values of the Effective Flange Width Coefficients for b_m and b_s for the Given Values of b/l_i

Figure 4.6.2.6.2-3—Cross-Sections and Corresponding Effective Flange Widths, b_e , for Flexure and Shear

Figure 4.6.2.6.2-4—Effective Flange Widths, b_n , for Normal Forces

4.6.2.6.3—Cast-in-Place Multicell Superstructures

The effective width for cast-in-place multi-web cellular superstructures may be taken to be as specified in Article 4.6.2.6.1, with each web taken to be a beam, or it may be taken to be the full width of the deck slab. In the latter case, the effects of shear lag in the end zones shall be investigated.

4.6.2.6.4—Orthotropic Steel Decks

The effective width need not be determined when using refined analysis as specified in Article 4.6.3.2.4. For simplified analysis, the effective width of the deck, including the deck plate and ribs, acting as the top flange of a longitudinal superstructure component or a transverse beam may be taken as:

- $L/B \geq 5$: fully effective
- $L/B < 5$: $b_{od} = \frac{1}{5}L$

where:

- L = span length of the orthotropic girder or transverse beam (in.)
- B = spacing between orthotropic girder web plates or transverse beams (in.)
- b_{od} = effective width of orthotropic deck (in.)

for strength limit states for positive and negative flexure. For service and fatigue limit states in regions of high shear, the effective deck width can be determined by refined analysis or other accepted approximate methods.

C4.6.2.6.4

Consideration of effective width of the deck plate can be avoided by application of refined analysis methods.

The procedures in *Design Manual for Orthotropic Steel Plate Deck Bridges* (AISC, 1963) may be used as an acceptable means of simplified analysis; however, it has been demonstrated that using this procedure can result in rib effective widths exceeding the rib spacing, which may be unconservative.

Tests (Dowling et al., 1977) have shown that for most practical cases, shear lag can be ignored in calculating the ultimate compressive strength of stiffened or unstiffened girder flanges (Lamas and Dowling, 1980) (Burgan and Dowling, 1985) (Jetteur et al., 1984) (Hindi, 1991). Thus, a flange may normally be considered to be loaded uniformly across its width. It is necessary to consider the flange effectiveness in greater detail only in the case of flanges with particularly large aspect ratios ($L/B < 5$) or particularly slender edge panels or stiffeners (Burgan and Dowling, 1985) (Hindi, 1991).

Consideration of inelastic behavior can increase the effective width as compared to elastic analysis. At ultimate loading, the region of the flange plate above the web can yield and spread the plasticity (and distribute

4.6.2.6.5—Transverse Floorbeams and Integral Bent Caps

For transverse floorbeams and for integral bent caps designed with a composite concrete deck slab, the effective flange width overhanging each side of the transverse floorbeam or bent cap web shall not exceed six times the least slab thickness or one-tenth of the span length. For cantilevered transverse floorbeams or integral bent caps, the span length shall be taken as two times the length of the cantilever span.

4.6.2.7—Lateral Wind Load Distribution in Girder System Bridges

4.6.2.7.1—I-Sections

In bridges with composite decks, noncomposite decks with concrete haunches, and other decks that can provide horizontal diaphragm action, wind load on the upper half of the outside beam, the deck, vehicles, barriers, and appurtenances shall be assumed to be directly transmitted to the deck, acting as a lateral diaphragm carrying this load to supports. Wind load on the lower half of the outside beam shall be assumed to be applied laterally to the lower flange.

For bridges with decks that cannot provide horizontal diaphragm action, the lever rule shall apply for distribution of the wind load to the top and bottom flanges.

Bottom and top flanges subjected to lateral wind load shall be assumed to carry that load to adjacent brace points by flexural action. Such brace points occur at wind bracing nodes or at cross-frames and diaphragm locations.

The lateral forces applied at brace points by the flanges shall be transmitted to the supports by one of the following load paths:

- Truss action of horizontal wind bracing in the plane of the flange;
- Frame action of the cross-frames or diaphragms transmitting the forces into the deck or the wind bracing in the plane of the other flange, and then by diaphragm action

stress) outward if the plate maintains local stability. Results from studies by Chen et al. (2005) on composite steel girders, which included several tub-girder bridges, indicate that the full slab width may be considered effective in both positive and negative moment regions.

Thus, orthotropic plates acting as flanges are considered fully effective for strength limit state evaluations from positive and negative flexure when the L/B ratio is at least 5. For the case of $L/B < 5$, only a width of one-fifth of the effective span should be considered effective. For service and fatigue limit states in regions of high shear, a special investigation into shear lag should be done.

C4.6.2.6.5

The provisions for the effective flange width for transverse floorbeams and integral bent caps are based on past successful practice, specified by Article 8.10.1.4 of the 2002 *AASHTO Standard Specifications for Highway Bridges*.

C4.6.2.7.1

Precast concrete plank decks and timber decks are not solid diaphragms and should not be assumed to provide horizontal diaphragm action unless evidence is available to show otherwise.

Unless a more refined analysis is made, the wind force, wind moment, horizontal force to be transmitted by diaphragms and cross-frames, and horizontal force to be transmitted by lateral bracing may be calculated as indicated below. This procedure is presented for beam bridges but may be adapted for other types of bridges.

The wind force, W , may be applied to the flanges of exterior members. For composite members and noncomposite members with cast-in-place concrete or orthotropic steel decks, W need not be applied to the top flange.

$$W = \frac{\eta_l \gamma P_D d}{2} \quad (\text{C4.6.2.7.1-1})$$

where:

- W = factored wind force per unit length applied to the flange (kip/ft)
- P_D = design horizontal wind pressure specified in Article 3.8.1 (ksf)
- d = depth of the member (ft)

- of the deck, or truss action of the wind bracing, to the supports; or
- Lateral bending of the flange subjected to the lateral forces and all other flanges in the same plane, transmitting the forces to the ends of the span; for example, where the deck cannot provide horizontal diaphragm action, and there is no wind bracing in the plane of either flange.

γ = load factor specified in Table 3.4.1-1 for the particular group loading combination

η_i = load modifier relating to ductility, redundancy, and operational importance as specified in Article 1.3.2.1

For the first two load paths, the maximum wind moment on the loaded flange may be determined as:

$$M_w = \frac{WL_b^2}{10} \quad (\text{C4.6.2.7.1-2})$$

where:

M_w = maximum lateral moment in the flange due to the factored wind loading (kip-ft)

W = factored wind force per unit length applied to the flange (kip/ft)

L_b = spacing of brace points (ft)

For the third load path, the maximum wind moment on the loaded flange may be computed as:

$$M_w = \frac{WL_b^2}{10} + \frac{WL^2}{8N_b} \quad (\text{C4.6.2.7.1-3})$$

where:

M_w = total lateral moment in the flange due to the factored wind loading (kip-ft)

W = factored wind force per unit length applied to the flange (kip/ft)

L_b = spacing of cross-frames or diaphragms (ft)

N_b = number of longitudinal members

L = span length (ft)

Eq. C4.6.2.7.1-3 is based on the assumption that cross-frames and diaphragms act as struts in distributing the wind force on the exterior flange to adjacent flanges. If there are no cross-frames or diaphragms, the first term should be taken as 0.0, and N_b should be taken as 1.0.

The horizontal wind force applied to each brace point may be calculated as:

$$P_w = WL_b \quad (\text{C4.6.2.7.1-4})$$

where:

P_w = lateral wind force applied to the brace point (kips)

W = wind force per unit length from Eq. C4.6.2.7.1-1 (kip/ft)

L_b = spacing of diaphragms or cross-frames (ft)

Lateral bracing systems required to support both flanges due to transfer of wind loading through diaphragms or cross-frames shall be designed for a horizontal force of $2P_w$ at each brace point.

4.6.2.7.2—Box Sections

One-quarter of the wind force on a box section shall be applied to the bottom flange of the exterior box beam. The section assumed to resist the wind force shall consist of the bottom flange and a part of the web as determined in Sections 5 and 6. The other three quarters of the wind force on a box section, plus the wind force on vehicles, barriers, and appurtenances, shall be assumed to be transmitted to the supports by diaphragm action of the deck.

Interbox lateral bracing shall be provided if the section assumed to resist the wind force is not adequate.

4.6.2.7.3—Construction

The need for temporary wind bracing during construction shall be investigated for I- and box-section bridges.

C4.6.2.7.3

The provisions of Articles 4.6.2.7.1 and 4.6.2.7.2 were developed for girder bridges after the deck is placed. The response of these structures to wind loads during construction before the deck placement is completed is significantly different from that of the completed bridge. The flow of wind around the structure and the resulting wind pressure acting on the individual girders is different. Another significant difference between bridges during construction and bridges in service is the short length of time expected between the erection of the girders and the placement of the deck. For the same probability of exceedance, the design wind speed decreases with the decrease in the time between the girder erection and the deck placement.

The AASHTO *Guide Specifications for Wind Loads on Bridges During Construction* modify the preceding wind-load provisions to account for these differences between completed bridges and bridges during construction. To determine if any wind bracing is necessary, the Guide Specifications may be used to perform an investigation of the inactive work zone wind load case between the completed erection of the girders and the placement of the concrete deck assuming no wind bracing is provided in the plane of either flange. The Guide Specifications may also be used to perform an investigation of the active work zone wind load case during the placement of the deck, if desired.

Article 4.2.2.1 of the Guide Specifications provides an approximate approach for calculating the lateral wind load moment at any point along any girder at any stage of construction in lieu of a refined analysis. For steel I-girders, the total calculated lateral wind moment, or sum of the global plus local lateral wind moment, may be proportioned to each flange according to the relative lateral stiffness of each flange, which assumes the cross-frames or diaphragms constrain the top and bottom girder flanges to deflect equally under the lateral wind loading. The horizontal wind force applied to each brace point may be calculated as specified in Article 4.2.2.2 of the Guide Specifications.

The reference cited in Article C5.5.4.3 may be consulted for the evaluation of the stability of precast,

prestressed concrete bridge girders seated on bearing pads and subject to wind loads during construction.

4.6.2.8—Seismic Lateral Load Distribution

4.6.2.8.1—Applicability

These provisions shall apply to diaphragms, cross-frames, and lateral bracing, which are part of the seismic lateral force resisting system in common slab-on-girder bridges in Seismic Zones 2, 3, and 4. The provisions of Article 3.10.9.2 shall apply to Seismic Zone 1.

4.6.2.8.2—Design Criteria

The Engineer shall demonstrate that a clear, straightforward load path to the substructure exists and that all components and connections are capable of resisting the imposed load effects consistent with the chosen load path.

The flow of forces in the assumed load path must be accommodated through all affected components and details including, but not limited to, flanges and webs of main beams or girders, cross-frames, connections, slab-to-girder interfaces, and all components of the bearing assembly from top flange interface through the confinement of anchor bolts or similar devices in the substructure.

The analysis and design of end diaphragms and cross-frames shall consider horizontal supports at an appropriate number of bearings. Slenderness and connection requirements of bracing members that are part of the lateral force resisting system shall comply with applicable provisions specified for main member design.

Members of diaphragms and cross-frames identified by the Designer as part of the load path carrying seismic forces from the superstructure to the bearings shall be designed and detailed to remain elastic, based on the applicable gross area criteria, under all design earthquakes, regardless of the type of bearings used. The applicable provisions for the design of main members shall apply.

4.6.2.8.3—Load Distribution

A viable load path shall be established to transmit lateral loads to the foundation based on the stiffness characteristics of the deck, diaphragms, cross-frames, and lateral bracing. Unless a more refined analysis is made, an approximate load path shall be assumed as noted below.

- In bridges with:
 - a concrete deck that can provide horizontal diaphragm action; or
 - a horizontal bracing system in the plane of the top flange,

C4.6.2.8.2

Diaphragms, cross-frames, lateral bracing, bearings, and substructure elements are part of a seismic load resisting system in which the lateral loads and performance of each element are affected by the strength and stiffness characteristics of the other elements. Past earthquakes have shown that when one of these elements responded in a ductile manner or allowed some movement, damage was limited. In the strategy taken herein, it is assumed that ductile plastic hinging in substructure is the primary source of energy dissipation. Alternative design strategies may be considered if approved by the Owner.

C4.6.2.8.3

A continuous path is necessary for the transmission of the superstructure inertia forces to the foundation. Concrete decks have significant rigidity in their horizontal plane, and in short to medium slab-on-girder spans, their response approaches a rigid body motion. Therefore, the lateral loading of the intermediate diaphragms and cross-frames is minimal.

Bearings do not usually resist load simultaneously, and damage to only some of the bearings at one end of a span is not uncommon. When this occurs, high load concentrations can result at the location of the other bearings, which should be taken into account in the

the lateral loads applied to the deck shall be assumed to be transmitted directly to the bearings through end diaphragms or cross-frames. The development and analysis of the load path through the deck or through the top lateral bracing, if present, shall utilize assumed structural actions analogous to those used for the analysis of wind loadings.

- In bridges that have:
 - decks that cannot provide horizontal diaphragm action and
 - no lateral bracing in the plane of the top flange,

the lateral loads applied to the deck shall be distributed through the intermediate diaphragms and cross-frames to the bottom lateral bracing or the bottom flange, and then to the bearings, and through the end diaphragms and cross-frames, in proportion to their relative rigidity and the respective tributary mass of the deck.

- If a bottom lateral bracing system is not present, and the bottom flange is not adequate to carry the imposed force effects, the first procedure shall be used, and the deck shall be designed and detailed to provide the necessary horizontal diaphragm action.

design of the end cross-frames or diaphragms. Also, a significant change in the load distribution among end cross-frame members may occur. Although studies of cyclic load behavior of bracing systems have shown that with adequate details, bracing systems can allow for ductile behavior, these design provisions require elastic behavior in end diaphragms (Astaneh-Asl and Goel, 1984) (Astaneh-Asl et al., 1985) (Haroun and Sheperd, 1986) (Goel and El-Tayem, 1986).

Because the end diaphragm is required to remain elastic as part of the identified load path, stressing of intermediate cross-frames need not be considered.

4.6.2.9—Analysis of Segmental Concrete Bridges

4.6.2.9.1—General

Elastic analysis and beam theory may be used to determine design moments, shears, and deflections. The effects of creep, shrinkage, and temperature differentials shall be considered as well as the effects of shear lag. Shear lag shall be considered in accordance with the provisions of Article 4.6.2.9.3.

For spans in excess of 250 ft, results of elastic analyses should be evaluated with consideration of possible variations in the modulus of elasticity of the concrete, variations in the concrete creep and shrinkage properties, and the impact of variations in the construction schedule on these and other design parameters.

4.6.2.9.2—Strut-and-Tie Models

Strut-and-tie models may be used for analysis in areas of load or geometrical discontinuity.

C4.6.2.9.1

Analysis of concrete segmental bridges requires consideration of variation of design parameters with time as well as a specific construction schedule and method of erection. This, in turn, requires the use of a computer program developed to trace the time-dependent response of segmentally erected, prestressed concrete bridges through construction and under service loads. Among the many programs developed for this purpose, several are in the public domain and may be purchased for a nominal amount, e.g., (Ketchum, 1986) (Shushkewich, 1986) (Danon and Gamble, 1977).

C4.6.2.9.2

See references for background on transverse analysis of concrete box girder bridges.

4.6.2.9.3—Effective Flange Width

Effective flange width for service load stress calculations may be determined by the provisions of Article 4.6.2.6.2.

The section properties for normal forces may be based on Figure 4.6.2.6.2-4 or determined by more rigorous analysis.

Bending, shear, and normal forces may be evaluated by using the corresponding factored resistances.

The capacity of a cross-section at the strength limit state may be determined by considering the full compression flange width effect.

4.6.2.9.4—Transverse Analysis

The transverse design of box girder segments for flexure shall consider the segment as a rigid box frame. Flanges shall be analyzed as variable depth sections, considering the fillets between the flanges and webs. Wheel loads shall be positioned to provide maximum moments, and elastic analysis shall be used to determine the effective longitudinal distribution of wheel loads for each load location. Consideration shall be given to the increase in web shear and other effects on the cross-section resulting from eccentric loading or unsymmetrical structure geometry.

The provisions of Articles 4.6.2.1 and 4.6.3.2, influence surfaces such as those by Homberg (1968) and Pucher (1964), or other elastic analysis procedures may be used to evaluate live load plus impact moment effects in the top flange of the box section.

Transverse elastic and creep shortening due to prestressing and shrinkage shall be considered in the transverse analysis.

The effect of secondary moments due to prestressing shall be included in stress calculations at the service limit state and construction evaluation. At the strength limit state, the secondary force effects induced by prestressing, with a load factor of 1.0, shall be added algebraically to the force effects due to factored dead and live loads and other applicable loads.

4.6.2.9.5—Longitudinal Analysis

4.6.2.9.5a—General

Longitudinal analysis of segmental concrete bridges shall consider a specific construction method and construction schedule as well as the time-related effects of concrete creep, shrinkage, and prestress losses.

The effect of secondary moments due to prestressing shall be included in stress calculations at the service limit state. At the strength limit state, the secondary force effects induced by prestressing, with a load factor of 1.0, shall be added algebraically to other applicable factored loads.

4.6.2.9.5b—Erection Analysis

Analysis of the structure during any construction stage shall consider the construction load combinations, stresses, and stability considerations specified in Article 5.12.5.3.

4.6.2.9.5c—Analysis of the Final Structural System

The provisions of Article 5.12.5.2.3 shall apply.

4.6.2.10—Equivalent Strip Widths for Box Culverts

4.6.2.10.1—General

This Article shall be applied to concrete culverts with depths of fill less than 2.0 ft and as specified in Article 3.6.1.2.6a.

C4.6.2.10.1

Design for depths of fill of 2.0 ft or greater are covered in Article 3.6.1.2.6.

4.6.2.10.2—Case 1: Traffic Travels Parallel to Span

When traffic travels primarily parallel to the span, culverts shall be analyzed for a single loaded lane with the single-lane multiple presence factor.

C4.6.2.10.2

Culverts are designed under the provisions of Section 12. Box culverts are normally analyzed as two-dimensional frames. Equivalent strip widths are used to simplify the analysis of the three-dimensional response to live loads. Eqs. 4.6.2.10.2-1 and 4.6.2.10.2-2 are based on research (McGrath et al., 2004) that investigated the forces in box culverts with spans up to 24.0 ft.

Strip widths for box culverts are expressed in terms of wheel loads. Box culvert spans are most commonly short, though not always, and design forces are typically controlled by single wheel effects.

The distribution widths are based on distribution of shear forces. Distribution widths for positive and negative moments are wider; however, using the narrower width in combination with a single-lane multiple presence factor provides designs adequate for multiple loaded lanes for all force effects.

Although past practice has been to ignore the distribution of live load with depth of fill, consideration of this effect, as presented in Eq. 4.6.2.10.2-2, produces a more accurate model of the changes in design forces with increasing depth of fill. The increased load length parallel to the span, as allowed by Eq. 4.6.2.10.2-2, may be conservatively neglected in design.

Wheel loads shall be distributed to the top slab for determining moment, thrust, and shear as follows:

Perpendicular to the span:

$$E = 28 + L_p + 0.72S \quad (4.6.2.10.2-1)$$

Parallel to the span:

$$E_{span} = L_T + LLDF(H) \quad (4.6.2.10.2-2)$$

where:

- E = equivalent distribution width perpendicular to span (in.)
- L_p = length of tire contact area perpendicular to span (l_t or w_t , see Articles 3.6.1.2.5 and 3.6.1.2.6) (in.)
- S = clear span (ft)
- E_{span} = equivalent distribution length parallel to span (in.)
- L_T = length of tire contact area parallel to span (l_t or w_t , see Articles 3.6.1.2.5 and 3.6.1.2.6) (in.)

$LLDF$ = factor for distribution of live load with depth of fill as specified in Article 3.6.1.2.6
 H = depth of fill from top of culvert to top of pavement (in.)

4.6.2.10.3—Case 2: Traffic Travels Perpendicular to Span

Traffic traveling perpendicular to the span shall consider multiple lane loadings with the appropriate multiple presence factor. When traffic travels perpendicular to the span, wheel loads shall be distributed to the top slab as follows:

Perpendicular to the span:

$$E = \frac{((Ax - 1) * Ax_{sp} + 28 + L_p + 0.72S)}{Ax} \quad (4.6.2.10.3-1)$$

Parallel to the span shall be per Eq. 4.6.2.10.2-2.

where:

Ax = number of axles in axle group
 Ax_{sp} = spacing of axles in axle group (in.)

Load effects per Equation 4.6.2.10.3-1 shall not be less than those calculated in accordance with Equation 4.6.2.10.2-1.

4.6.2.10.4—Precast Box Culverts

For precast box culverts with top slabs having span-to-thickness ratios (s/t) of 18 or less and segment lengths greater than or equal to 4 ft in length, shear transfer across the joint need not be provided.

For precast box culverts not satisfying the requirements noted above, the design shall incorporate one of the following:

- Provide the culvert with a means of shear transfer between the adjacent sections. Shear transfer may be provided by pavement, soil fill, or a physical connection between adjacent sections.
- Design the section ends as edgebeams in accordance with the provisions of Article 4.6.2.1.4b using the distribution width computed from Eq. 4.6.2.10.2-1. The distribution width shall not exceed the length between two adjacent joints.

C4.6.2.10.3

Culverts with traffic traveling perpendicular to the span can have two or more trucks on the same design strip at the same time. This must be considered, with the appropriate multiple presence factor, in analysis of the culvert structural response.

When vehicles travel perpendicular to the span, the wheel loads from adjacent axles often interact. The equations in this Article address this interaction.

C4.6.2.10.4

Precast box culverts manufactured in accordance with AASHTO M 259 are often installed with joints that do not provide a means of direct shear transfer across the joints of adjacent sections under service load conditions. This practice is based on research (James, 1984) (Frederick, et al., 1988) which indicated significant shear transfer may not be necessary under service loading. The response of the sections tested was typified by small deflections and strains indicating that cracking did not occur under service wheel loads with no earth cover and that the demand on the section was lower than predicted by the design, which was based conservatively on a cracked section. While there are no known service issues with installation of standard box sections without means of shear transfer across joints, analysis (McGrath et al., 2004) shows that stresses are substantially higher when a box culvert is subjected to a live load at a free edge than when loaded away from a free edge.

However, research performed on precast box culverts that were loaded at the edge of the section (Garg et al., 2007) (Abolmaali and Garg; 2008a, 2008b) has shown that no means of load transfer across the joint is required when the live load is distributed per

Articles 4.6.2.10.2 and 4.6.2.10.3 and the top slab of the box culvert is designed in accordance with Article 5.7.3. The tested boxes were shown to have significantly more shear strength than predicted by Article 5.7.3.

For box culverts outside of the normal ASTM/AASHTO dimensional requirements, some fill or pavement will likely provide sufficient shear transfer to distribute live load to adjacent box sections without shear keys to avoid higher stresses due to edge loading. Otherwise, for box culverts outside of ASTM/AASHTO dimensional requirements with zero depth of cover, and no pavement, soil, or other means of shear transfer such as shear keys, designers should design the culvert section for the specified reduced distribution widths lacking a more rigorous design method.

4.6.3—Refined Methods of Analysis

4.6.3.1—General

Refined methods listed in Article 4.4 may be used for the analysis of bridges. In such analyses, consideration shall be given to aspect ratios of elements, positioning and number of nodes, and other features of topology that may affect the accuracy of the analytical solution.

A structurally continuous railing, barrier, or median, acting compositely with the supporting components, may be considered to be structurally active at service and fatigue limit states.

When a refined method of analysis is used, a table of live load distribution coefficients for extreme force effects in each span shall be provided in the contract documents to aid in permit issuance and rating of the bridge.

4.6.3.2—Decks

4.6.3.2.1—General

Unless otherwise specified, flexural and torsional deformation of the deck shall be considered in the

C4.6.3.1

The number of possible locations for positioning the design vehicular live load will be large when determining the extreme force effect in an element using a refined method of analysis. The following are variable:

- The location of the design lanes when the available deck width contains a fraction of a design lane width;
- The design lanes actually used;
- The longitudinal location of the design vehicular live load in each lane;
- The longitudinal axle spacing of the design vehicular live load; and
- The transverse location of the design vehicular live load in each lane.

This provision reflects the experimentally observed response of bridges. This source of stiffness has traditionally been neglected but exists and may be included, provided that full composite behavior is assured.

These live load distribution coefficients should be provided for each combination of component and lane.

C4.6.3.2.1

In many solid decks, the wheel load carrying contribution of torsion is comparable to that of flexure.

analysis but vertical shear deformation may be neglected.

Locations of flexural discontinuity through which shear may be transmitted should be modeled as hinges.

In the analysis of decks that may crack and/or separate along element boundaries when loaded, Poisson's ratio may be neglected. The wheel loads shall be modeled as patch loads distributed over an area, as specified in Article 3.6.1.2.5, taken at the contact surface. This area may be extended by the thickness of the wearing surface, integral or nonintegral, on all four sides. When such extension is utilized, the thickness of the wearing surface shall be reduced for any possible wear at the time of interest. Other extended patch areas may be utilized with the permission of the Owner, provided that such extended area is consistent with the assumptions in, and application of, a particular refined method of analysis.

4.6.3.2.2—Isotropic Plate Model

For the purpose of this section, bridge decks that are solid, have uniform or close to uniform depth, and whose stiffness is close to equal in every in-plane direction shall be considered isotropic.

4.6.3.2.3—Orthotropic Plate Model

In orthotropic plate modeling, the flexural rigidity of the elements may be uniformly distributed along the cross-section of the deck. Where the torsional stiffness of the deck is not contributed solely by a solid plate of uniform thickness, the torsional rigidity should be established by physical testing, three-dimensional analysis, or generally accepted and verified approximations.

4.6.3.2.4—Refined Orthotropic Deck Model

Refined analysis of orthotropic deck structures subjected to direct wheel loads should be accomplished using a detailed three-dimensional shell or solid finite element structural model. The structural model should include all components and connections and consider local structural stress at fatigue prone details as shown in Table 6.6.1.2.3-1. Structural modeling techniques that utilize the following simplifying assumptions may be applied:

- Linear elastic material behavior;
- Small-deflection theory;
- Plane sections remain plane;
- Neglect residual stresses; and
- Neglect imperfections and weld geometry.

Large torsional moments exist in the end zones of skewed girder bridges due to differential deflection. In most deck types, shear stresses are rather low, and their contribution to vertical deflection is not significant. In-plane shear deformations, which gave rise to the concept of effective width for composite bridge decks, should not be neglected.

C4.6.3.2.2

Analysis is rather insensitive to small deviations in constant depth, such as those due to superelevation, crown, and haunches. In slightly cracked concrete slabs, even a large difference in the reinforcement ratio will not cause significant changes in load distribution.

The torsional stiffness of the deck may be estimated using Eq. C4.6.2.2.1-1, with b equal to 1.0.

C4.6.3.2.3

The accuracy of the orthotropic plate analysis is sharply reduced for systems consisting of a small number of elements subjected to concentrated loads.

C4.6.3.2.4

Further guidance on evaluating local structural stresses using finite element modeling is provided in *Manual for Design, Construction, and Maintenance of Orthotropic Steel Bridges* (FHWA, 2012).

Meshing shall be sufficiently detailed to calculate local stresses at weld toes and to resolve the wheel patch pressure loading with reasonable accuracy.

4.6.3.3—Beam-Slab Bridges

4.6.3.3.1—General

The aspect ratio of finite elements and grid panels should not exceed 5.0. Abrupt changes in size and/or shape of finite elements and grid panels should be avoided.

Nodal loads shall be statically equivalent to the actual loads being applied.

C4.6.3.3.1

More restrictive limits for aspect ratio may be specified for the software used.

In the absence of other information, the following guidelines may be used at the discretion of the Engineer:

- A minimum of five, and preferably nine, nodes per beam span should be used.
- For finite element analyses involving plate and beam elements, it is preferable to maintain the relative vertical distances between various elements. If this is not possible, longitudinal and transverse elements may be positioned at the midthickness of the plate-bending elements, provided that the eccentricities are included in the equivalent properties of those sections that are composite.
- For grid analysis or finite element and finite difference analyses of live load, the slab shall be assumed to be effective for stiffness in both positive and negative flexure. In a filled or partially filled grid system, composite section properties should be used.
- In finite element analysis, an element should have membrane capability with discretization sufficient to properly account for shear lag. The force effects so computed should be applied to the appropriate composite or noncomposite section for computing resistance.
- For longitudinal composite members in grid analyses, stiffness should be computed by assuming a width of the slab to be effective, but it need not be less than that specified in Article 4.6.2.6.
- The St. Venant torsional inertia may be determined using the appropriate equation from Article C4.6.2.2.1. Transformation of concrete and steel to a common material should be on the basis of shear modulus, G , which can be taken as $G = 0.5E/(1+\mu)$. It is recommended that the St. Venant rigidity of composite sections utilize only one-half of the effective width of the flexural section, as described above, before transformation. For the analysis of composite loading conditions using plate and eccentric beam structural analysis models, the St. Venant torsional inertia of steel I-girders should be calculated using Eq. C4.6.2.2.1-1 without the

consideration of any torsional interaction with the composite deck.

4.6.3.3.2—2D Grid and Plate and Eccentric Beam Analyses of Curved and/or Skewed Steel I-Girder Bridges

C4.6.3.3.2

For the analysis of curved and/or skewed steel I-girder bridges where either $I_C > 1$ or $I_S > 0.3$, the warping rigidity of the I-girders shall be considered in 2D grid and plate and eccentric beam methods of structural analysis,

Unless otherwise stated, this Article applies to curved and/or skewed steel I-girder bridges analyzed by 2D grid or plate and eccentric beam analysis. In a 2D grid analysis or a 2D plate and eccentric beam analysis of a steel I-girder bridge, the use of only the St. Venant torsional stiffness, GJ/L_b , can result in a substantial underestimation of the girder torsional stiffness. This is due to neglect of the contribution of warping rigidity to the overall girder torsional stiffness. When the contribution from the girder warping rigidity is not accounted for in the analysis, the vertical deflections in curved I-girder systems can be substantially overestimated due to the coupling between the girder torsional and flexural response where $I_C > 1$. Furthermore, the cross-frame forces can be substantially underestimated in straight or curved skewed I-girder bridges due to the underestimation of the torsional stiffness provided by the girders where $I_S > 0.3$, particularly for bridges in the noncomposite condition.

in which:

$$I_C = \frac{15,000}{R(n_{cf} + 1)m} \quad (4.6.3.3.2-1)$$

$$I_S = \frac{w_g \tan \theta}{L_s} \quad (4.6.3.3.2-2)$$

where:

- I_C = I-girder bridge connectivity index, taken equal to the maximum of the values of Eq. 4.6.3.3.2-1 determined for each span of the bridge
- m = bridge type constant, equal to 1 for simple-span bridges or bridge units, and equal to 2 for continuous-span bridges or bridge units, determined at the loading condition under consideration
- n_{cf} = number of intermediate cross-frames or diaphragms within the individual spans of the bridge or bridge unit at the loading condition under consideration
- R = minimum radius of curvature at the centerline of the bridge cross-section throughout the length of the bridge or bridge unit at the loading condition under consideration (ft)
- I_S = bridge skew index, taken equal to the maximum of the values of Eq. 4.6.3.3.2-2 determined for each span of the bridge
- L_s = span length at the centerline (ft)
- w_g = maximum width between the girders on the outside of the bridge cross-section at the completion of the construction or at an intermediate stage of the steel erection (ft)
- θ = maximum skew angle of the bearing lines at the end of a given span, measured from a line taken perpendicular to the span centerline (degrees)

White et al. (2012) present an approximate method of considering the girder warping rigidity, applicable for I-girder bridges or bridge units in their final constructed condition as well as for intermediate noncomposite conditions during steel erection. For the analysis of composite loading conditions using plate and eccentric beam structural analysis models, it is sufficient to calculate the warping rigidity of the I-girders, EC_w , using solely the steel cross-section with Eq. C6.9.4.1.3-1 and without the consideration of any composite torsional interaction with the composite deck.

Other methods of considering the warping rigidity of steel I-girders include the explicit use of open-section thin-walled beam theory or the use of a general-purpose 3D finite element analysis in which the I-girder is modeled as described previously. Additional information on the modeling of torsion in I-girder bridges may be found in AASHTO/NSBA (2019).

When conducting 2D grid or plate and eccentric beam analyses, cross-frames are modeled as equivalent beam elements. End moments and shears in the equivalent beam elements obtained from the structural analysis are then converted into cross-frame member forces through an idealized truss analysis. Studies have shown that these common postprocessing procedures can produce reasonably accurate predictions of the cross-frame forces in noncomposite systems, particularly for straight bridges with normal supports or limited skews, assuming the modeling procedures outlined in Article 4.6.3.3.4a are implemented (Park et al., 2021). However, these procedures may lead to more significant errors in the predictions of the cross-frame forces in composite systems, regardless of bridge

4.6.3.3.3—Curved Steel Bridges

Refined analysis methods should be used for the analysis of curved steel bridges unless the Engineer ascertains that approximate analysis methods are appropriate according to the provisions of Article 4.6.2.2.4.

geometry, when compared to the predictions of these forces from more rigorous 3D analyses. Article C4.6.3.3.4a offers methods to improve force predictions in cross-frames in 2D grid or plate and eccentric beam analysis models.

C4.6.3.3.3

Refined analysis methods, identified in Article 4.4, are generally computer-based. The finite strip and finite element methods have been the most common. The finite strip method is less rigorous than the finite element method and has fallen into disuse with the advent of more powerful computers. Finite element programs may provide grid analyses using a series of beam elements connected in a plane. Refinements of the grid model may include offset elements. Frequently, the torsional warping degree-of-freedom is not available in beam elements. The finite element method may be applied to a three-dimensional model of the superstructure. A variety of elements may be used in this type of model. The three-dimensional model may be made capable of recognizing warping torsion by modeling each girder cross-section with a series of elements.

The stiffness of supports, including lateral restraint such as integral abutments or integral piers, should be recognized in the analysis. Since bearing restraint is offset from the neutral axis of the girders, large lateral forces at the bearings often occur and may create significant bending in the girders, which may lead to lower girder moments than would be computed if the restraints were not present. The Engineer should ascertain that any such benefit recognized in the design will be present throughout the useful life of the bridge.

Loads may be applied directly to the structural model, or applied to influence lines or influence surfaces. Only where small-deflection elastic solutions are used are influence surfaces or influence lines appropriate. The Engineer should ascertain that dead loads are applied as accurately as possible.

4.6.3.3.4—Cross-Frames and Diaphragms

4.6.3.3.4a—2D Grid and Plate and Eccentric Beam Analyses

When modeling a cross-frame as an equivalent beam element in 2D grid or plate and eccentric beam analyses, both the cross-frame flexure and shear deformation shall be considered in determining the equivalent beam element stiffness.

When determining the equivalent beam stiffness, the influence of connection and/or gusset plate details shall be considered in the calculation of the equivalent axial rigidity of single-angle and tee-section members as specified in Article 4.6.3.3.4c.

C4.6.3.3.4a

Due to their predominant action as trusses, cross-frames generally exhibit substantial beam shear deformations when modeled using equivalent beam elements in a structural analysis. The modeling of cross-frames using Euler–Bernoulli beam elements, which neglect beam shear deformation, in 2D grid or plate and eccentric beam analyses typically results in substantial misrepresentation of their physical stiffness properties. Timoshenko beam elements, which are able to represent both flexure and shear deformations, provide a significantly improved approximation of the cross-frame stiffnesses (White et al., 2012).

The overall response of cross-frames in noncomposite systems during construction has been shown to be quite different than the response in composite systems subjected to live load traffic (Park et al., 2021). This is largely attributed to the presence of the concrete deck and the influence of truck position. As such, special consideration should be made when incorporating the concrete deck in 2D analysis models.

For bridges with widely spaced cross-frames or diaphragms, it may be desirable to use notional transverse beam members to model the deck when using grid analysis methods. The number of such beams is to some extent discretionary. The significance of shear lag in the transverse beam-slab width as it relates to lateral load distribution can be evaluated qualitatively by varying the stiffness of the beam-slab elements within reasonable limits and observing the results. Such a sensitivity study often shows this effect is not significant.

As an alternative to the notional beam approach, it may also be desirable to consider the transverse stiffness of the concrete deck in grid analysis models through a combined effective stiffness of the equivalent cross-frame beam members. That is to say, the shear, flexural, and torsional contributions of the deck are included in the section properties for the equivalent cross-frame beams. In this case, it is appropriate to approximate the effective width of the concrete deck as the tributary width perpendicular to the cross-frame of interest, or simply the typical intermediate cross-frame spacing for most practical conditions.

When using this approach, it is prudent to also consider the composite deck when postprocessing the analysis results. In composite systems, top struts are generally more lightly loaded members, and diagonal members in X-type cross-frames seldom have equal-and-opposite force magnitudes.

To better represent the distribution of forces through a cross-frame panel, internal forces can be resolved to a composite system consisting of the cross-frame and the concrete deck, as demonstrated in Figure C4.6.3.3.4a-1 where V , M_1 , and M_2 represent the corresponding internal shear and end moments in the cross-frame. Furthermore, H is the centroidal distance between the bottom strut and the deck, V_{deck} is the portion of the internal shear resisted by the deck at a cross-frame, and V_{CF} is the portion of the internal shear resisted by the cross-frame panel. The distribution of V can be approximated based on the relative flexural stiffness of the deck and cross-frame (Park et al., 2021).

The distribution of V_{CF} to the top and bottom nodes of the cross-frame panel also has a direct influence on the force predictions in the diagonal members, particularly for X-type cross-frames. Traditionally, a “50-50” distribution is assumed, which produces equal-and-opposite forces in the diagonal members. This assumption has been shown to work well for noncomposite systems but can lead to more substantial errors in composite systems, given the complex load-

induced deformations commonly observed in cross-frames for these conditions.

This observed behavior and subsequent improvement methods are applicable for both 2D grid and plate and eccentric beam analysis methods. Thus, for all 2D analysis methods utilizing equivalent cross-frame beams, the Engineer must give special consideration to the force distribution in cross-frame diagonal members. As a more conservative measure compared to the “50-50” distribution, each cross-frame diagonal can be designed for the full shear force, V_{CF} , obtained from the analysis model. Even with this measure, cross-frame diagonal forces can still be underestimated when compared to the results obtained from 3D analysis models (Park et al., 2021). Figure C4.6.3.3.4a-1 presents a method to improve the postprocessing of 2D grid model results in composite systems by considering the load distribution to the concrete deck, an element not explicitly represented in the grid model.

Figure C4.6.3.3.4a-1—Recommended Postprocessing of Internal Forces from an Equivalent Beam Cross-Frame Frame in a 2D Grid Model of a Composite System

The easiest way to establish extreme live-load force effects in cross-frames and diaphragms in refined analyses is by using influence surfaces analogous to those developed for the main longitudinal members.

4.6.3.3.4b—3D Analyses

When modeling a cross-frame as a truss member in 3D analyses, the influence of eccentric connection and/or gusset plate details shall be considered in the calculation of the equivalent axial stiffness of single-angle and tee-section cross-frame members as specified in Article 4.6.3.3.4c.

C4.6.3.3.4b

Alternatively, modeling cross-frames as eccentric beam elements in 3D models has also been shown to produce accurate results. In this method, connection and gusset plates are modeled as beam elements with equivalent section properties, and the eccentric load paths are explicitly considered (Park et al., 2021).

4.6.3.3.4c—Equivalent Axial Rigidity of Single-Angle and Tee-Section Cross-Frame Members

In lieu of a more refined analysis, the equivalent axial rigidity of single-angle and tee-section cross-frame members should be taken as $0.65AE$ in the analysis model for the noncomposite condition during construction. In lieu of a more refined analysis, the equivalent axial rigidity of single-angle and tee-section cross-frame members should be taken as $0.75AE$ in the analysis model for the composite condition.

C4.6.3.3.4c

The axial rigidity of single-angle and tee-section cross-frame members is generally reduced due to end connection eccentricities (Wang et al., 2012) (Reichenbach et al., 2021) (Park et al., 2023). The recommended modification factors inherently consider different bridge geometries and connection details and are to be assigned uniformly to all cross-frame members in a bridge.

The use of single reduction factors for the investigation of both the noncomposite and composite conditions is based on a statistical representation of an analytical data set. Using a single value of $0.65AE$ for the stiffness reduction factor is generally conservative for the investigation of the noncomposite condition during construction but may be unconservative for the investigation of the composite condition with respect to the strength and fatigue limit states. Conversely, using a single value of $0.75AE$ is generally conservative for the investigation of the composite condition but may be unconservative for the investigation of the noncomposite condition during construction, particularly for the evaluation of stability bracing requirements in Article 6.7.4.2.2. If it is desired or more convenient to use a single value in the analysis, a value should be chosen based upon engineering judgment considering the specifics of the bridge under consideration.

4.6.3.4—Cellular and Box Bridges

A refined analysis of cellular bridges may be made by any of the analytic methods specified in Article 4.4, except the yield line method, which accounts for the two dimensions seen in plan view and for the modeling of boundary conditions. Models intended to quantify torsional warping and/or transverse frame action should be fully three-dimensional.

For single box cross-sections, the superstructure may be analyzed as a spine beam for both flexural and torsional effects. A steel box should not be considered to be torsionally rigid unless internal bracing is provided to maintain the box cross-section. The transverse position of bearings shall be modeled.

4.6.3.5—Truss Bridges

A refined plane frame or space frame analysis shall include consideration for the following:

- Composite action with the deck or deck system;
- Continuity among the components;
- Force effects due to self-weight of components, change in geometry due to deformation, and axial offset at panel points; and

C4.6.3.5

Load applied to deck or floorbeams instead of to truss joints will yield results that more completely quantify out-of-plane actions.

Experience has shown that dead load force effects calculated using either plane frame or space frame analysis in a truss with properly cambered primary and secondary members and detailed to minimize eccentricity at joints, will be quite close to those calculated by the conventional approximations. In many cases, a complete three-dimensional frame analysis may

- In-plane and out-of-plane buckling of components including original out-of-straightness, continuity among the components, and the effect axial forces present in those components.

Out-of-plane buckling of the upper chords of pony truss bridges shall be investigated. If the truss derives its lateral stability from transverse frames, of which the floorbeams are a part, the deformation of the floorbeams due to vehicular loading shall be considered.

4.6.3.6—Arch Bridges

The provisions of Article 4.6.3.5 shall apply where applicable.

The effect of the extension of cable hangers shall be considered in the analysis of an arch tie.

Where not controlled through proper detailing, rib shortening should be investigated.

The use of large deflection analysis of arches of longer spans should be considered in lieu of the moment magnification correction as specified in Article 4.5.3.2.2c.

When the distribution of stresses between the top and bottom chords of trussed arches is dependent on the manner of erection, the manner of erection shall be indicated in the contract documents.

4.6.3.7—Cable-Stayed Bridges

The distribution of force effects to the components of a cable-stayed bridge may be determined by either spatial or planar structural analysis if justified by consideration of tower geometry, number of planes of stays, and the torsional stiffness of the deck superstructure.

Cable-stayed bridges shall be investigated for nonlinear effects that may result from:

- The change in cable sag at all limit states,
- Deformation of deck superstructure and towers at all limit states, and
- Material nonlinearity at the extreme event limit states.

Cable sag may be investigated using an equivalent member modeled as a chord with modified modulus of elasticity given by Eq. 4.6.3.7-1 for instantaneous

be the only way to accurately calculate forces in secondary members, particularly live load force effects.

C4.6.3.6

Rib shortening and arch design and construction are discussed by Nettleton (1977).

Any single-step correction factor cannot be expected to accurately model deflection effects over a wide range of stiffnesses.

If a hinge is provided at the crown of the rib in addition to hinges at the abutment, the arch becomes statically determinate, and stresses due to change of temperature and rib shortening are essentially eliminated.

Arches may be analyzed, designed, and constructed as hinged under dead load or portions of dead load and as fixed at some hinged locations for the remaining design loads.

In trussed arches, considerable latitude is available in design for distribution of stresses between the top and bottom chords dependent on the manner of erection. In such cases, the manner of erection should be indicated in the contract documents.

C4.6.3.7

Nonlinear effects on cable-stayed bridges are treated in several texts, e.g., (Podolny and Scalzi, 1986) (Troitsky, 1977), and a report by the ASCE Committee on Cable Suspended Bridges (ASCE, 1991), from which the particular forms of Eqs. 4.6.3.7-1 and 4.6.3.7-2 were taken.

stiffness and Eq. 4.6.3.7-2, applied iteratively, for changing cable loads.

$$E_{MOD} = E \left[1 + \frac{EAW^2(\cos \alpha)^5}{12H^3} \right]^{-1} \quad (4.6.3.7-1)$$

$$E_{MOD} = E \left[1 + \frac{(H_1 + H_2)EAW^2(\cos \alpha)^5}{24H_1^2H_2^2} \right]^{-1} \quad (4.6.3.7-2)$$

where:

- E = modulus of elasticity of the cable (ksi)
- W = total weight of cable (kip)
- A = cross-sectional area of cable (in.²)
- α = angle between cable and horizontal (degrees)
- H, H_1, H_2 = horizontal component of cable force (kip)

The change in force effects due to deflection may be investigated using any method that satisfies the provisions of Article 4.5.3.2.1 and accounts for the change in orientation of the ends of cable stays.

Cable-stayed bridges shall be investigated for the loss of any one cable stay.

4.6.3.8—Suspension Bridges

Force effects in suspension bridges shall be analyzed by the large deflection theory for vertical loads. The effects of wind loads shall be analyzed, with consideration of the tension stiffening of the cables. The torsional rigidity of the deck may be neglected in assigning forces to cables, suspenders, and components of stiffening trusses.

C4.6.3.8

In the past, short suspension bridges have been analyzed by conventional small-deflection theories. Correction factor methods have been used on short- to moderate-span bridges to account for the effect of deflection, which is especially significant for calculating deck system moments. Any contemporary suspension bridge would have a span such that the large deflection theory should be used. Suitable computer programs are commercially available. Therefore, there is little rationale to use anything other than the large deflection solution.

For the same economic reasons, the span would probably be long enough that the influence of the torsional rigidity of the deck, combined with the relatively small effect of live load compared to dead load, will make the simple sum-of-moments technique suitable to assign loads to the cables and suspenders and usually even to the deck system, e.g., a stiffening truss.

4.6.4—Redistribution of Negative Moments in Continuous Beam Bridges

4.6.4.1—General

The Owner may permit the redistribution of force effects in multispans, multibeam, or girder superstructures. Inelastic behavior shall be restricted to the flexure of beams or girders, and inelastic behavior due to shear and/or uncontrolled buckling shall not be permitted. Redistribution of loads shall not be considered in the transverse direction.

The reduction of negative moments over the internal supports due to the redistribution shall be accompanied by a commensurate increase in the positive moments in the spans.

4.6.4.2—Refined Method

The negative moments over the support, as established by linear elastic analysis, may be decreased by a redistribution process considering the moment-rotation characteristics of the cross-section or by a recognized mechanism method. The moment-rotation relationship shall be established using material characteristics, as specified herein, and/or verified by physical testing.

4.6.4.3—Approximate Procedure

In lieu of the analysis described in Article 4.6.4.2, simplified redistribution procedures for concrete and steel beams, as specified in Sections 5 and 6, respectively, may be used.

4.6.5—Stability

The investigation of stability shall utilize the large deflection theory.

4.6.6—Analysis for Temperature Gradient

Where determination of force effects due to vertical temperature gradient is required, the analysis should consider axial extension, flexural deformation, and internal stresses.

Gradients shall be as specified in Article 3.12.3.

C4.6.6

The response of a structure to a temperature gradient can be divided into three effects as follows:

- *Axial Expansion*—This is due to the uniform component of the temperature distribution that should be considered simultaneously with the uniform temperature specified in Article 3.12.2. It may be calculated as:

$$T_{UG} = \frac{1}{A_c} \int \int T_G dw dz \quad (C4.6.6-1)$$

The corresponding uniform axial strain is:

$$\epsilon_u = \alpha (T_{UG} + T_u) \quad (C4.6.6-2)$$

- *Flexural Deformation*—Because plane sections remain plane, a curvature is imposed on the superstructure to accommodate the linearly variable component of the temperature gradient. The rotation per unit length corresponding to this curvature may be determined as:

$$\phi = \frac{\alpha}{I_c} \int \int T_G z dw dz = \frac{1}{R} \quad (C4.6.6-3)$$

If the structure is externally unrestrained, i.e., simply supported or cantilevered, no external force effects are developed due to this superimposed deformation.

The axial strain and curvature may be used in both flexibility and stiffness formulations. In the former, ϵ_u may be used in place of P/AE , and ϕ may be used in place of M/EI in traditional displacement calculations. In the latter, the fixed-end force effects for a prismatic frame element may be determined as:

$$N = EA_c \epsilon_u \quad (\text{C4.6.6-4})$$

$$M = EI_c \phi \quad (\text{C4.6.6-5})$$

An expanded discussion with examples may be found in Ghali and Neville (1989). Strains induced by other effects, such as shrinkage and creep, may be treated in a similar manner.

- *Internal Stress*—Using the sign convention that compression is positive, internal stresses in addition to those corresponding to the restrained axial expansion and/or rotation may be calculated as:

$$\sigma_E = E[\alpha T_G - \alpha T_{UG} - \phi z] \quad (\text{C4.6.6-6})$$

where:

- T_G = temperature gradient ($\Delta^\circ\text{F}$)
- T_{UG} = temperature averaged across the cross-section ($^\circ\text{F}$)
- T_u = uniform specified temperature ($^\circ\text{F}$)
- A_c = cross-section area—transformed for steel beams (in.^2)
- I_c = inertia of cross-section—transformed for steel beams (in.^4)
- α = coefficient of thermal expansion ($\text{in./in./}^\circ\text{F}$)
- E = modulus of elasticity (ksi)
- R = radius of curvature (ft)
- w = width of element in cross-section (in.)
- z = vertical distance from center of gravity of cross-section (in.)

For example, the flexural deformation part of the gradient flexes a prismatic superstructure into a segment of a circle in the vertical plane. For a two-span structure with span length, L , in ft, the unrestrained beam would lift off from the central support by $\Delta = 6 L^2/R$ in. Forcing the beam down to eliminate Δ would develop a moment whose value at the pier would be:

$$M_c = \frac{3}{2} EI_c \phi \quad (\text{C4.6.6-7})$$

Therefore, the moment is a function of the beam rigidity and imposed flexure. As rigidity approaches 0.0 at the strength limit state, M_c tends to disappear. This behavior also indicates the need for ductility to ensure structural integrity as rigidity decreases.

4.7—DYNAMIC ANALYSIS

4.7.1—Basic Requirements of Structural Dynamics

4.7.1.1—General

For analysis of the dynamic behavior of bridges, the stiffness, mass, and damping characteristics of the structural components shall be modeled.

The minimum number of degrees-of-freedom included in the analysis shall be based upon the number of natural frequencies to be obtained and the reliability of the assumed mode shapes. The model shall be compatible with the accuracy of the solution method. Dynamic models shall include relevant aspects of the structure and the excitation. The relevant aspects of the structure may include the:

- Distribution of mass;
- Distribution of stiffness; and
- Damping characteristics.

The relevant aspects of excitation may include the:

- Frequency of the forcing function;
- Duration of application; and
- Direction of application.

4.7.1.2—Distribution of Masses

The modeling of mass shall be made with consideration of the degree of discretization in the model and the anticipated motions.

C4.7.1.1

Typically, analysis for vehicle- and wind-induced vibrations is not to be considered in bridge design. Although a vehicle crossing a bridge is not a static situation, the bridge is analyzed by statically placing the vehicle at various locations along the bridge and applying a dynamic load allowance, as specified in Article 3.6.2, to account for the dynamic responses caused by the moving vehicle. However, in flexible bridges and long slender components of bridges that may be excited by bridge movement, dynamic force effects may exceed the allowance for impact given in Article 3.6.2. In most observed bridge vibration problems, the natural structural damping has been very low. Flexible continuous bridges may be especially susceptible to vibrations. These cases may require analysis for moving live load.

If the number of degrees-of-freedom in the model exceeds the number of dynamic degrees-of-freedom used, a standard condensation procedure may be employed.

Condensation procedures may be used to reduce the number of degrees-of-freedom prior to the dynamic analysis. Accuracy of the higher modes can be compromised with condensation. Thus if higher modes are required, such procedures should be used with caution.

The number of frequencies and mode shapes necessary to complete a dynamic analysis should be estimated in advance or determined as an early step in a multistep approach. Having determined that number, the model should be developed to have a larger number of applicable degrees-of-freedom.

Sufficient degrees-of-freedom should be included to represent the mode shapes relevant to the response sought. One rule-of-thumb is that there should be twice as many degrees-of-freedom as required frequencies.

The number of degrees-of-freedom and the associated masses should be selected in a manner that approximates the actual distributive nature of mass. The number of required frequencies also depends on the frequency content of the forcing function.

C4.7.1.2

The distribution of stiffness and mass should be modeled in a dynamic analysis. The discretization of the model should account for geometric and material variation in stiffness and mass.

The selection of the consistent or lump mass formulation is a function of the system and the response sought and is difficult to generalize. For distributive mass systems modeled with polynomial shape functions in which the mass is associated with distributive stiffness, such as a beam, a consistent mass formulation is recommended (Paz, 1985). In lieu of a consistent

4.7.1.3—Stiffness

The bridge shall be modeled to be consistent with the degrees-of-freedom chosen to represent the natural modes and frequencies of vibration. The stiffness of the elements of the model shall be defined to be consistent with the bridge being modeled.

4.7.1.4—Damping

Equivalent viscous damping may be used to represent energy dissipation.

4.7.1.5—Natural Frequencies

For the purpose of Article 4.7.2, and unless otherwise specified by the Owner, elastic undamped natural modes and frequencies of vibration shall be used. For the purpose of Articles 4.7.4 and 4.7.5, all relevant damped modes and frequencies shall be considered.

4.7.2—Elastic Dynamic Responses

4.7.2.1—Vehicle-Induced Vibration

When an analysis for dynamic interaction between a bridge and the live load is required, the Owner shall specify and/or approve surface roughness, speed, and dynamic characteristics of the vehicles to be employed for the analysis. Impact shall be derived as a ratio of the extreme dynamic force effect to the corresponding static force effect.

formulation, lumped masses may be associated at the translational degrees-of-freedom, a manner that approximates the distributive nature of the mass (Clough and Penzian, 1975).

For systems with distributive mass associated with larger stiffness, such as in-plane stiffness of a bridge deck, the mass may be properly modeled as lumped. The rotational inertia effects should be included where significant.

C4.7.1.3

In seismic analysis, nonlinear effects which decrease stiffness, such as inelastic deformation and cracking, should be considered.

Reinforced concrete columns and walls in Seismic Zones 2, 3, and 4 should be analyzed using cracked section properties. For this purpose, a moment of inertia equal to one-half that of the uncracked section may be used.

C4.7.1.4

Damping may be neglected in the calculation of natural frequencies and associated nodal displacements. The effects of damping should be considered where a transient response is sought.

Suitable damping values may be obtained from field measurement of induced free vibration or by forced vibration tests. In lieu of measurements, the following values may be used for the equivalent viscous damping ratio:

- Concrete construction: two percent
- Welded and bolted steel construction: one percent
- Timber: five percent

C4.7.2.1

In no case shall the dynamic load allowance used in design be less than 50 percent of the dynamic load allowance specified in Table 3.6.2.1-1, except that no reduction shall be allowed for deck joints.

The limitation on the dynamic load allowance reflects the fact that deck surface roughness is a major factor in vehicle/bridge interaction and that it is difficult to estimate long-term deck deterioration effects thereof at the design stage.

The proper application of the provision for reducing the dynamic load allowance is:

$$IM_{CALC} \geq 0.5IM_{Table\ 3-6} \quad (C4.7.2.1-1)$$

not:

$$\left(1 + \frac{IM}{100}\right)_{CALC} \geq 0.5 \left(1 + \frac{IM}{100}\right) \quad (C4.7.2.1-2)$$

4.7.2.2—Wind-Induced Vibration

4.7.2.2.1—Wind Velocities

For critical or essential structures which may be expected to be sensitive to wind effects, the location and magnitude of extreme pressure and suction values shall be established by simulated wind tunnel tests.

4.7.2.2.2—Dynamic Effects

Wind-sensitive structures shall be analyzed for dynamic effects, such as buffeting by turbulent or gusting winds, and unstable wind-structure interaction, such as galloping and flutter. Slender or torsionally flexible structures shall be analyzed for lateral buckling, excessive thrust, and divergence.

4.7.2.2.3—Design Considerations

Oscillatory deformations under wind that may lead to excessive stress levels, structural fatigue, and user inconvenience or discomfort shall be avoided. Bridge decks, cable stays, and hanger cables shall be protected against excessive vortex and wind-rain-induced oscillations. Where practical, the employment of dampers shall be considered to control excessive dynamic responses. Where dampers or shape modification are not practical, the structural system shall be changed to achieve such control.

C4.7.2.2.3

Additional information on design for wind may be found in Scanlan (1975); Simiu and Scanlan (1978); Basu and Chi (1981a); Basu and Chi (1981b); ASCE (1961); and ASCE (1991).

4.7.3—Inelastic Dynamic Responses

4.7.3.1—General

During a major earthquake or ship collision, energy may be dissipated by one or more of the following mechanisms:

- Elastic and inelastic deformation of the object that may collide with the structure;
- Inelastic deformation of the structure and its attachments;

- Permanent displacement of the masses of the structure and its attachments; and
- Inelastic deformation of special-purpose mechanical energy dissipators.

4.7.3.2—Plastic Hinges and Yield Lines

For the purpose of analysis, energy absorbed by inelastic deformation in a structural component may be assumed to be concentrated in plastic hinges and yield lines. The location of these sections may be established by successive approximation to obtain a lower-bound solution for the energy absorbed. For these sections, moment–rotation hysteresis curves may be determined by using verified analytic material models.

4.7.4—Analysis for Earthquake Loads

4.7.4.1—General

Minimum analysis requirements for seismic effects shall be as specified in Table 4.7.4.3.1-1.

For the modal methods of analysis, specified in Articles 4.7.4.3.2 and 4.7.4.3.3, the design response spectrum specified in Article 3.10.4.1 shall be used.

Bridges in Seismic Zone 1 need not be analyzed for seismic loads, regardless of their operational classification and geometry. However, the minimum requirements specified in Articles 4.7.4.4 and 3.10.9 shall apply.

4.7.4.2—Single-Span Bridges

Seismic analysis is not required for single-span bridges, regardless of seismic zone.

Connections between the bridge superstructure and the abutments shall be designed for the minimum force requirements as specified in Article 3.10.9.

Minimum support length requirements shall be satisfied at each abutment, as specified in Article 4.7.4.4.

4.7.4.3—Multispan Bridges

4.7.4.3.1—Selection of Method

For multispan structures, the minimum analysis requirements shall be as specified in Table 4.7.4.3.1-1 in which:

*	=	no seismic analysis required
UL	=	uniform load elastic method
SM	=	single-mode elastic method
MM	=	multimode elastic method
TH	=	time-history method

C4.7.4.2

A single-span bridge is comprised of a superstructure unit supported by two abutments with no intermediate piers.

C4.7.4.3.1

The selection of the method of analysis depends on seismic zone, regularity, and operational classification of the bridge.

Regularity is a function of the number of spans and the distribution of weight and stiffness. Regular bridges have less than seven spans; no abrupt or unusual changes in weight, stiffness, or geometry; and no large changes in these parameters from span to span or support to support, abutments excluded. A more rigorous analysis procedure may be used in lieu of the recommended minimum.

Table 4.7.4.3.1-1—Minimum Analysis Requirements for Seismic Effects

Seismic Zone	Single-Span Bridges	Multispan Bridges					
		Ordinary Bridges		Recovery Bridges		Critical Bridges	
		regular	irregular	regular	irregular	regular	irregular
1	No seismic analysis required	*	*	*	*	*	*
2		SM/UL	SM	SM/UL	MM	MM	MM
3		SM/UL	MM	MM	MM	MM	TH
4		SM/UL	MM	MM	MM	TH	TH

Except as specified below, bridges satisfying the requirements of Table 4.7.4.3.1-2 may be taken as “regular” bridges. Bridges not satisfying the requirements of Table 4.7.4.3.1-2 shall be taken as “irregular” bridges.

Table 4.7.4.3.1-2—Regular Bridge Requirements

Parameter	Value				
Number of spans	2	3	4	5	6
Maximum subtended angle for a curved bridge	90°	90°	90°	90°	90°
Maximum span length ratio from span to span	3	2	2	1.5	1.5
Maximum bent/pier stiffness ratio from span to span, excluding abutments	—	4	4	3	2

Curved bridges comprised of multiple simple spans shall be considered to be “irregular” if the subtended angle in plan is greater than 20 degrees. Such bridges shall be analyzed by either the multimode elastic method or the time-history method.

A curved continuous-girder bridge may be analyzed as if it were straight, provided all of the following requirements are satisfied:

- The bridge is “regular” as defined in Table 4.7.4.3.1-2, except that for a two-span bridge the maximum span length ratio from span to span must not exceed 2;
- The subtended angle in plan is not greater than 90 degrees; and
- The span lengths of the equivalent straight bridge are equal to the arc lengths of the curved bridge.

If these requirements are not satisfied, then curved continuous-girder bridges must be analyzed using the actual curved geometry.

4.7.4.3.2—Single-Mode Methods of Analysis

4.7.4.3.2a—General

Either of the two single-mode methods of analysis specified herein may be used where appropriate.

4.7.4.3.2b—Single-Mode Spectral Method

The single-mode method of spectral analysis shall be based on the fundamental mode of vibration in either the longitudinal or transverse direction. For regular bridges, the fundamental modes of vibration in the horizontal plane coincide with the longitudinal and transverse axes of the bridge structure. This mode shape may be found by applying a uniform horizontal load to the structure and calculating the corresponding deformed shape. The natural period may be calculated by equating the maximum potential and kinetic energies associated with the fundamental mode shape. The amplitude of the displaced shape may be found from the design spectral acceleration coefficient, S_a , for the period of the structure, and the corresponding spectral displacement. This amplitude shall be used to determine force effects.

C4.7.4.3.2b

The single-mode spectral analysis method described in the following steps may be used for both transverse and longitudinal earthquake motions. Examples illustrating its application are given in AASHTO (1983) and ATC (1981).

- Calculate the static displacements, $v_s(x)$, due to an assumed uniform loading, p_o , as shown in Figure C4.7.4.3.2b-1:

Figure C4.7.4.3.2b-1—Bridge Deck Subjected to Assumed Transverse and Longitudinal Loading

- Calculate factors α , β , and γ as:

$$\alpha = \int v_s(x) dx \quad (C4.7.4.3.2b-1)$$

$$\beta = \int w(x) v_s(x) dx \quad (C4.7.4.3.2b-2)$$

$$\gamma = \int w(x) v_s^2(x) dx \quad (C4.7.4.3.2b-3)$$

where:

- p_o = a uniform load arbitrarily set equal to 1.0 (kip/ft)
- $v_s(x)$ = deformation corresponding to p_o (ft)
- $w(x)$ = nominal, unfactored dead load of the bridge superstructure and tributary substructure (kip/ft)

The computed factors, α , β , and γ , have units of (ft²), (kip-ft), and (kip-ft²), respectively.

- Calculate the period of the bridge as:

$$T_m = 2\pi \sqrt{\frac{\gamma}{p_o g \alpha}} \quad (\text{C4.7.4.3.2b-4})$$

where:

g = acceleration of gravity (ft/s²)

- Calculate the equivalent static earthquake loading $p_e(x)$ as:

$$p_e(x) = \frac{\beta S_a}{\gamma} w(x) v_s(x) \quad (\text{C4.7.4.3.2b-5})$$

where:

S_a = design spectral acceleration coefficient at the period of the structure, T_m

$p_e(x)$ = the intensity of the equivalent static seismic loading applied to represent the primary mode of vibration (kip/ft)

- Apply loading $p_e(x)$ to the structure, and determine the resulting member force effects.

4.7.4.3.2c—Uniform Load Method

The uniform load method shall be based on the fundamental mode of vibration in either the longitudinal or transverse direction of the base structure. The period of this mode of vibration shall be taken as that of an equivalent single mass-spring oscillator. The stiffness of this equivalent spring shall be calculated using the maximum displacement that occurs when an arbitrary uniform lateral load is applied to the bridge. The design spectral acceleration coefficient, S_a , at the period of the structure shall be used to calculate the equivalent uniform seismic load from which seismic force effects are found.

C4.7.4.3.2c

The uniform load method, described in the following steps, may be used for both transverse and longitudinal earthquake motions. It is essentially an equivalent static method of analysis that uses a uniform lateral load to approximate the effect of seismic loads. The method is suitable for regular bridges that respond principally in their fundamental mode of vibration. Whereas all displacements and most member forces are calculated with good accuracy, the method is known to overestimate the transverse shears at the abutments by up to 100 percent. If such conservatism is undesirable, then the single-mode spectral analysis method specified in Article 4.7.4.3.2b is recommended.

- Calculate the static displacements, $v_s(x)$, due to an assumed uniform load, p_o , as shown in Figure C4.7.4.3.2b-1. The uniform loading, p_o , is applied over the length of the bridge; it has units of force per unit length and may be arbitrarily set equal to 1.0. The static displacement, $v_s(x)$, has units of length.
- Calculate the bridge lateral stiffness, K , and total weight, W , from the following expressions:

$$K = \frac{p_o L}{v_{s,MAX}} \quad (\text{C4.7.4.3.2c-1})$$

$$W = \int w(x) dx \quad (\text{C4.7.4.3.2c-2})$$

where:

- L = total length of the bridge (ft)
- $v_{s,MAX}$ = maximum value of $v_s(x)$ (ft)
- $w(x)$ = nominal, unfactored dead load of the bridge superstructure and tributary substructure (kip/ft)

The weight should take into account structural elements and other relevant loads including, but not limited to, pier caps, abutments, columns, and footings. Other loads, such as live loads, may be included. Generally, the inertia effects of live loads are not included in the analysis; however, the probability of a large live load being on the bridge during an earthquake should be considered when designing bridges with high live-to-dead load ratios that are located in metropolitan areas where traffic congestion is likely to occur.

- Calculate the period of the bridge, T_m , using the expression:

$$T_m = 2\pi \sqrt{\frac{W}{gK}} \quad (C4.7.4.3.2c-3)$$

where:

- g = acceleration of gravity (ft/s²)
- Calculate the equivalent static earthquake loading, p_e , from the expression:

$$p_e = \frac{S_a W}{L} \quad (C4.7.4.3.2c-4)$$

where:

- S_a = design spectral acceleration coefficient at the period of the structure, T_m
- p_e = equivalent uniform static seismic loading per unit length of bridge applied to represent the primary mode of vibration (kip/ft)
- Calculate the displacements and member forces for use in design either by applying p_e to the structure and performing a second static analysis or by scaling the results of the first step above by the ratio p_e/p_o .

4.7.4.3.3—Multimode Spectral Method

C4.7.4.3.3

The multimode spectral analysis method shall be used for bridges in which coupling occurs in more than one of the three coordinate directions within each mode of vibration. As a minimum, linear dynamic analysis using a three-dimensional model shall be used to represent the structure.

The number of modes included in the analysis should be at least three times the number of spans in the model. The design seismic response spectrum as specified in Article 3.10.4 shall be used for each mode.

The member forces and displacements may be estimated by combining the respective response quantities (moment, force, displacement, or relative displacement) from the individual modes by the Complete Quadratic Combination (CQC) method.

Member forces and displacements obtained using the CQC combination method are generally adequate for most bridge systems (Wilson et al., 1981).

If the CQC method is not readily available, alternative methods include the square root of the sum of the squares method (SRSS), but this method is best suited for combining responses from well-separated modes. For closely spaced modes, the absolute sum of the modal responses should be used.

4.7.4.3.4—Time-History Method

C4.7.4.3.4

4.7.4.3.4a—General

C4.7.4.3.4a

Any step-by-step time-history method of analysis used for either elastic or inelastic analysis shall satisfy the requirements of Article 4.7.

The sensitivity of the numerical solution to the size of the time step used for the analysis shall be determined. A sensitivity study shall also be carried out to investigate the effects of variations in assumed material hysteretic properties.

The time histories of input acceleration used to describe the earthquake loads shall be selected in accordance with Article 4.7.4.3.4b.

Rigorous methods of analysis are required for critical structures, which are defined in Article 3.10.3, and/or those that are geometrically complex or close to active earthquake faults. Time-history methods of analysis are recommended for this purpose, provided care is taken with both the modeling of the structure and the selection of the input time histories of ground acceleration.

4.7.4.3.4b—Acceleration Time Histories

C4.7.4.3.4b

Developed time histories shall have characteristics that are representative of the seismic environment of the site and the local site conditions.

Response-spectrum-compatible time histories shall be used as developed from representative recorded motions. Analytical techniques used for spectrum matching shall be demonstrated to be capable of achieving seismologically realistic time series that are similar to the time series of the initial time histories selected for spectrum matching.

Where recorded time histories are used, they shall be scaled to the approximate level of the design response spectrum in the period range of significance. Each time history shall be modified to be response-spectrum-compatible using the time-domain procedure.

At least three response-spectrum-compatible time histories shall be used for each component of motion in representing the design earthquake (ground motions having seven percent probability of exceedance in 75 years). All three orthogonal components (x, y, and z) of design motion shall be input simultaneously when conducting a nonlinear time-history analysis. The design actions shall be taken as the maximum response calculated for the three ground motions in each principal direction.

Characteristics of the seismic environment to be considered in selecting time histories include:

- tectonic environment (e.g., subduction zone; shallow crustal faults);
- earthquake magnitude;
- type of faulting (e.g., strike-slip; reverse; normal);
- seismic-source-to-site distance;
- local site conditions; and
- design or expected ground-motion characteristics (e.g., design response spectrum, duration of strong shaking, and special ground-motion characteristics such as near-fault characteristics).

Dominant earthquake magnitudes and distances, which contribute principally to the probabilistic design response spectra at a site, as determined from national ground-motion maps, can be obtained from deaggregation information on the USGS website at <https://geohazards.cr.usgs.gov>.

It is desirable to select time histories that have been recorded under conditions similar to the seismic conditions at the site as listed above, but compromises are usually required because of the multiple attributes of the

If a minimum of seven time histories are used for each component of motion, the design actions may be taken as the mean response calculated for each principal direction.

For near-field sites ($D < 6$ mi), the recorded horizontal components of motion that are selected should represent a near-field condition and should be transformed into principal components before making them response-spectrum-compatible. The major principal component should then be used to represent motion in the fault-normal direction and the minor principal component should be used to represent motion in the fault-parallel direction.

seismic environment and the limited data bank of recorded time histories. Selection of time histories having similar earthquake magnitudes and distances, within reasonable ranges, are especially important parameters because they have a strong influence on response spectral content, response spectral shape, duration of strong shaking, and near-source ground-motion characteristics. It is desirable that selected recorded motions be somewhat similar in overall ground-motion level and spectral shape to the design spectrum to avoid using very large scaling factors with recorded motions and very large changes in spectral content in the spectrum-matching approach. If the site is located within six miles of an active fault, then intermediate-to-long-period ground-motion pulses that are characteristic of near-source time histories should be included if these types of ground-motion characteristics could significantly influence structural response. Similarly, the high short-period spectral content of near-source vertical ground motions should be considered.

Ground-motion modeling methods of strong motion seismology are being increasingly used to supplement the recorded ground-motion database. These methods are especially useful for seismic settings for which relatively few actual strong motion recordings are available, such as in the central and eastern United States. Through analytical simulation of the earthquake rupture and wave propagation process, these methods can produce seismologically reasonable time series.

Response spectrum matching approaches include methods in which time series adjustments are made in the time domain (Lilhanand and Tseng, 1988) (Abrahamson, 1992) and those in which the adjustments are made in the frequency domain (Gasparini and Vanmarcke, 1976) (Silva and Lee, 1987) (Bolt and Gregor, 1993). Both of these approaches can be used to modify existing time histories to achieve a close match to the design response spectrum while maintaining fairly well the basic time-domain character of the recorded or simulated time histories. To minimize changes to the time-domain characteristics, it is desirable that the overall shape of the spectrum of the recorded time history not be greatly different from the shape of the design response spectrum, and that the time history initially be scaled so that its spectrum is at the approximate level of the design spectrum before spectrum matching.

Where three-component sets of time histories are developed by simple scaling rather than spectrum matching, it is difficult to achieve a comparable aggregate match to the design spectra for each component of motion when using a single scaling factor for each time-history set. It is desirable, however, to use a single scaling factor to preserve the relationship between the components. Approaches for dealing with this scaling issue include:

- use of a higher scaling factor to meet the minimum aggregate match requirement for

one component while exceeding it for the other two;

- use of a scaling factor to meet the aggregate match for the most critical component with the match somewhat deficient for other components; and
- compromising on the scaling by using different factors as required for different components of a time-history set.

While the second approach is acceptable, it requires careful examination and interpretation of the results and possibly dual analyses for application of the higher horizontal component in each principal horizontal direction.

The requirements for the number of time histories to be used in nonlinear inelastic dynamic analysis and for the interpretation of the results take into account the dependence of response on the time-domain character of the time histories (duration, pulse shape, pulse sequencing) in addition to their response spectral content.

Additional guidance on developing acceleration time histories for dynamic analysis may be found in publications by the Caltrans Seismic Advisory Board Adhoc Committee (CSABAC) on Soil-Foundation-Structure Interaction (1999) and the U.S. Army Corps of Engineers (2000). CSABAC (1999) also provides detailed guidance on modeling the spatial variation of ground motion between bridge piers and the conduct of seismic soil-foundation-structure interaction (SFSI) analyses. Both spatial variations of ground motion and SFSI may significantly affect bridge response. Spatial variations include differences between seismic wave arrival times at bridge piers (wave passage effect), ground-motion incoherence due to seismic wave scattering, and differential site response due to different soil profiles at different bridge piers. For long bridges, all forms of spatial variations may be important. For short bridges, limited information appears to indicate that wave passage effects and incoherence are, in general, relatively unimportant in comparison to effects of differential site response (Shinozuka et al., 1999) (Martin, 1998). Somerville et al. (1999) provide guidance on the characteristics of pulses of ground motion that occur in time histories in the near-fault region.

4.7.4.4—Minimum Support Length Requirements

Support lengths at expansion bearings without restrainers, STUs, or dampers shall either accommodate the greater of the maximum displacement calculated in accordance with the provisions of Article 4.7.4.3, except for bridges in Zone 1, or a percentage of the empirical support length, N , specified by Eq. 4.7.4.4-1. Otherwise, longitudinal restrainers complying with Article 3.10.9.5 shall be provided. Bearings restrained for longitudinal

C4.7.4.4

Support lengths are equal to the length of the overlap between the girder and the seat as shown in Figure C4.7.4.4-1. To satisfy the minimum values for N in this Article, the overall seat width will be larger than N by an amount equal to movements due to prestress shortening, creep, shrinkage, and thermal expansion/contraction. The minimum value for N given in Eq. 4.7.4.4-1 includes an arbitrary allowance for cover concrete at the end of the

movement shall be designed in compliance with Article 3.10.9. The percentages of N , applicable to each seismic zone, shall be as specified in Table 4.7.4.4-1.

The empirical support length shall be taken as:

$$N = (8 + 0.02L + 0.08H)(1 + 0.000125S^2) \quad (4.7.4.4-1)$$

where:

- N = minimum support length measured normal to the centerline of bearing (in.)
- L = length of the bridge deck to the adjacent expansion joint, or to the end of the bridge deck; for hinges within a span, L shall be the sum of the distances to either side of the hinge; for single-span bridges, L equals the length of the bridge deck (ft)
- H = for abutments, average height of columns supporting the bridge deck from the abutment to the next expansion joint (ft); for columns and/or piers, column or pier height (ft); for hinges within a span, average height of the adjacent two columns or piers (ft); 0.0 for single-span bridges (ft)
- S = skew of support measured from line normal to span (degrees)

Table 4.7.4.4-1—Percentage, N , by Zone and Acceleration Coefficient, A_s

Zone	Acceleration Coefficient, A_s	Percent, N
1	<0.05	≥ 75
1	≥ 0.05	100
2	All Applicable	150
3	All Applicable	150
4	All Applicable	150

4.7.4.5— P - Δ Requirements

The displacement of any column or pier in the longitudinal or transverse direction shall satisfy:

$$\Delta P_u < 0.25\phi M_n \quad (4.7.4.5-1)$$

in which:

$$\Delta = R_d \Delta_e \quad (4.7.4.5-2)$$

- If $T < 1.25T_s$, then:

$$R_d = \left(1 - \frac{1}{R}\right) \frac{1.25T_s}{T} + \frac{1}{R} \quad (4.7.4.5-3)$$

- If $T \geq 1.25T_s$, then:

$$R_d = 1 \quad (4.7.4.5-4)$$

girder and face of the seat. If above average cover is used at these locations, N should be increased accordingly.

Figure C4.7.4.4-1—Support Length, N

C4.7.4.5

Bridges subject to earthquake ground motion may be susceptible to instability due to P - Δ effects. Inadequate strength can result in ratcheting of structural displacements to larger and larger values causing excessive ductility demand on plastic hinges in the columns, large residual deformations, and possibly collapse. The maximum value for Δ given in this Article is intended to limit the displacements such that P - Δ effects will not significantly affect the response of the bridge during an earthquake.

P - Δ effects lead to a loss in strength once yielding occurs in the columns of a bridge. In severe cases, this can result in the force-displacement relationship having a negative slope once yield is fully developed. The value for Δ given by Eq. 4.7.4.5-1 is such that this reduction in strength is limited to 25 percent of the yield strength of the pier or bent.

in which:

$$T_S = S_{D1}/S_{DS} \text{ (s)}$$

where:

Δ = displacement of the point of contraflexure in the column or pier relative to the point of fixity for the foundation (ft)

Δ_e = displacement calculated from elastic seismic analysis (in.)

T = period of fundamental mode of vibration (s)

R = R -factor specified in Article 3.10.7

P_u = axial load on column or pier (kip)

ϕ = flexural resistance factor for column specified in Article 5.11.4.1.2

M_n = nominal flexural strength of column or pier calculated at the axial load on the column or pier (kip-ft)

S_{D1} = value as defined in Article 3.10.6

S_{DS} = 90 percent of peak S_a value

4.7.5—Analysis for Collision Loads

Where permitted by the provisions of Section 3, dynamic analysis for ship collision may be replaced by an equivalent static elastic analysis. Where an inelastic analysis is specified, the effect of other loads that may also be present shall be considered.

4.7.6—Analysis of Blast Effects

As a minimum, bridge components analyzed for blast forces should be designed for the dynamic effects resulting from the blast pressure on the structure. The results of an equivalent static analysis shall not be used for this purpose.

C4.7.6

Localized spall and breach damage should be accounted for when designing bridge components for blast forces. Data available at the time these provisions were developed (winter 2010) are not sufficient to develop expressions for estimating the extent of spall/breach in concrete columns; however, spall and breach damage can be estimated for other types of components using guidelines found in Department of Defense (2008a).

The highly impulsive nature of blast loads warrants the consideration of inertial effects during the analysis of a structural component. Past research has demonstrated that, in general, an equivalent static analysis is not acceptable for the design of any structural member subjected to blast loads (Department of Defense; 2008a, 2002) (Bounds, 1998) (ASCE, 1997). Information on designing structures to resist blast loads may be found in ASCE (1997); Sections 2 and 3 of AASHTO's *Bridge Security Guidelines* (2022); Department of Defense (2008a); Conrath et al. (1999); Biggs (1964); and Bounds (1998).

4.8—ANALYSIS BY PHYSICAL MODELS

4.8.1—Scale Model Testing

To establish and/or to verify structural behavior, the Owner may require the testing of scale models of structures and/or parts thereof. The dimensional and material properties of the structure, as well as its boundary conditions and loads, shall be modeled as accurately as possible. For dynamic analysis, inertial scaling, load/excitation, and damping functions shall be applied as appropriate. For strength limit state tests, factored dead load shall be simulated. The instrumentation shall not significantly influence the response of the model.

4.8.2—Bridge Testing

Existing bridges may be instrumented and results obtained under various conditions of traffic and/or environmental loads or load tested with special-purpose vehicles to establish force effects and/or the load-carrying capacity of the bridge.

C4.8.2

These measured force effects may be used to project fatigue life, to serve as a basis for similar designs, to establish permissible weight limits, to aid in issuing permits, or to establish a basis of prioritizing rehabilitation or retrofit.

APPENDIX A4—DECK SLAB DESIGN TABLE

Table A4-1 may be used in determining the design moments for different girder arrangements. The following assumptions and limitations were used in developing this table and should be considered when using the listed values for design:

- The moments are calculated using the equivalent strip method as applied to concrete slabs supported on parallel girders.
- Multiple presence factors and the dynamic load allowance are included in the tabulated values.
- See Article 4.6.2.1.6 for the distance between the center of the girders to the location of the design sections for negative moments in the deck. Interpolation between the listed values may be used for distances other than those listed in Table A4-1.
- The moments are applicable for decks supported on at least three girders and having a width of not less than 14.0 ft between the centerlines of the exterior girders.
- The moments represent the upper bound for the moments in the interior regions of the slab and, for any specific girder spacing, were taken as the maximum value calculated, assuming different number of girders in the bridge cross-section. For each combination of girder spacing and number of girders, the following two cases of overhang width were considered:

- (a) Minimum total overhang width of 21.0 in. measured from the center of the exterior girder, and
- (b) Maximum total overhang width equal to the smaller of 0.625 times the girder spacing and 6.0 ft.

A railing system width of 21.0 in. was used to determine the clear overhang width. For other widths of railing systems, the difference in the moments in the interior regions of the deck is expected to be within the acceptable limits for practical design.

- The moments do not apply to the deck overhangs and the adjacent regions of the deck that need to be designed taking into account the provisions of Article A13.4.1.
- It was found that the effect of two 25^k axles of the tandem, placed at 4.0 ft from each other, produced maximum effects under each of the tires approximately equal to the effect of the 32^k truck axle. The tandem produces a larger total moment, but this moment is spread over a larger width. It was concluded that repeating calculations with a different strip width for the tandem would not result in a significant difference.

Table A4-1—Maximum Live Load Moments per Unit Width, kip-ft/ft

S	Positive Moment	Negative Moment							
		Distance from Centerline of Girder to Design Section for Negative Moment							
		0.0 in.	3 in.	6 in.	9 in.	12 in.	18 in.	24 in.

SECTION 5

CONCRETE STRUCTURES

Commentary is opposite the text it annotates.

5.1—SCOPE

The provisions in this Section apply to the design of bridge and ancillary structures constructed of normal weight or lightweight concrete and reinforced with steel bars, welded wire reinforcement, and/or prestressing strands, bars, or wires. The provisions are based on design concrete compressive strengths varying from 2.4 ksi to 10.0 ksi for normal weight and lightweight concrete, except where higher strengths not exceeding 15.0 ksi are allowed for normal weight concrete. The exceptions are noted in the specific articles and tabulated in Appendix C5.

The provisions of this Section characterize regions of concrete structures by their behavior as B- (beam or Bernoulli) Regions or D- (disturbed or discontinuity) Regions, as defined in Article 5.2. The characterization of regions into B-Regions and D-Regions is discussed in Article 5.5.1.

The provisions of this Section combine and unify the requirements for reinforced and prestressed concrete.

A brief outline for the design of some routine concrete components is contained in Appendix A5.

C5.1

These Specifications use kips and ksi units. Some other specifications, such as ACI 318, use pound and psi units. For most variables the conversion is obvious, but for those which have the form $N\sqrt{f'_c}$, the conversion is

$\frac{N\sqrt{f'_c}}{\sqrt{1,000}}$. For commonly used values of N , the relation

between psi and ksi is given below:

N , psi	N , ksi
1	0.0316
2	0.0632
3	0.0948
4	0.126
6	0.190
7.5	0.237
12	0.379

5.2—DEFINITIONS

Adhesive Anchor—A post-installed anchor, inserted into hardened concrete with an anchor hole diameter not greater than 1.5 times the anchor diameter, that transfers loads to the concrete by characteristic bond of the anchor system as defined in ACI 318.

Anchor—Steel element either cast into concrete or post-installed into a hardened concrete member and used to transmit applied loads to the concrete. Cast-in-place anchors include headed bolts, hooked bolts (J- or L-bolt), and headed studs. Post-installed anchors include expansion anchors, undercut anchors, and adhesive anchors. Steel elements for adhesive anchors include threaded rods, deformed reinforcing bars, or internally threaded steel sleeves with external deformations.

Anchor Pullout Strength—The strength corresponding to the anchoring device or a major component of the device sliding out from the concrete without breaking out a substantial portion of the surrounding concrete.

Anchorage—In post-tensioning, a mechanical device used to anchor the tendon to the concrete; in pretensioning, a device used to anchor the tendon until the concrete has reached a predetermined strength, and the prestressing force has been transferred to the concrete; for reinforcing bars, a length of reinforcement, or a mechanical anchor or hook, or combination thereof at the end of a bar needed to transfer the force carried by the bar into the concrete.

Anchorage Blister—A build-out area in the web, flange, or flange-web junction for the incorporation of tendon anchorage fittings.

Anchorage Zone—The portion of the structure in which the prestressing force is transferred from the anchorage device onto the local zone of the concrete, and then distributed more widely into the general zone of the structure.

At Jacking—At the time of tensioning the prestressing tendons.

At Loading—The maturity of the concrete when loads are applied. Such loads include prestressing forces and permanent loads but generally not live loads.

At Transfer—Immediately after the transfer of prestressing force to the concrete.

Beam or Bernoulli Region (B-Region)—Regions of concrete members in which Bernoulli's hypothesis of straight-line strain profiles, linear for bending and uniform for shear, applies. (See Article 5.5.1.2 for more detail.)

Blanketed Strand—See *Debonded Strand*.

Bonded Tendon—A tendon that is bonded to the concrete, either directly or by means of grouting.

Bursting Force—Tensile forces in the concrete in the vicinity of the transfer or anchorage of prestressing forces.

Cast-in-Place Anchor—A headed bolt, headed stud, or hooked bolt installed before placing concrete.

Cast-in-Place Concrete—Concrete placed in its final location in the structure while still in a plastic state.

Closely Spaced Anchorages—Anchorage devices are defined as closely spaced if their center-to-center spacing does not exceed 1.5 times the width of the anchorage devices in the direction considered.

Closure—A placement of cast-in-place concrete used to connect two or more previously cast portions of a structure.

Composite Construction—Concrete components or concrete and steel components interconnected to respond to force effects as a unit.

Compression-Controlled Section—A cross-section in which the net tensile strain in the extreme tension steel at nominal resistance is less than or equal to the compression-controlled strain limit.

Compression-Controlled Strain Limit—The net tensile strain in the extreme tension steel at balanced strain conditions. See Article 5.6.2.1.

Concrete Breakout Strength—The strength corresponding to a volume of concrete surrounding the anchor or group of anchors separating from the member.

Concrete Cover—The specified minimum distance between the surface of the reinforcing bars, strands, post-tensioning ducts, anchorages, or other embedded items, and the surface of the concrete.

Concrete Pryout Strength—The strength corresponding to formation of a concrete spall behind short, stiff anchors displaced in the direction opposite to the applied shear force.

Confinement—A condition where the disintegration of the concrete under compression is prevented by the development of lateral and/or circumferential forces such as may be provided by appropriate reinforcement, steel or composite tubes, or similar devices.

Confinement Anchorage—Anchorage for a post-tensioning tendon that functions on the basis of containment of the concrete in the local anchorage zone by special reinforcement.

Creep—Time-dependent deformation of concrete under permanent load.

Curvature Friction—Friction resulting from the tendon moving against the duct when tensioned due to the curvature of the duct.

Debonded Strand—A pretensioned prestressing strand that is bonded for a portion of its length and intentionally debonded elsewhere through the use of mechanical or chemical means. Also called shielded or blanketed strand.

Deck Slab—A solid concrete slab resisting and distributing wheel loads to the supporting components.

Decompression—The stage at which the compressive stresses, induced by prestress, are overcome by the tensile stresses.

Deep Component—Components in which the distance from the point of 0.0 shear to the face of the support is less than $2d$ or components in which a load causing more than one third of the shear at a support is closer than $2d$ from the face of the support.

Design Concrete Compressive Strength—The nominal compressive strength of concrete specified for the work and assumed for design and analysis of new structures.

Deviation Saddle—A concrete block build-out in a web, flange, or web-flange junction used to control the geometry of, or to provide a means for changing direction of, external tendons.

Development Length—The distance required to develop the specified strength of a reinforcing bar or prestressing strand.

Diabolo—A formed void in a concrete deviation saddle or diaphragm in a shape to align and direct an external tendon through the horizontal and vertical tendon profile required for the design.

Direct Loading/Supporting—Application of a load or use of a support external to the member, as in the case of point or uniform loads applied directly to the deck surface, simply-supported girder ends, bent (pier) cap supported on pinned columns.

Disturbed or Discontinuity Region (D-Region)—Regions of concrete members encompassing abrupt changes in geometry or concentrated forces in which strain profiles more complex than straight lines exist (See Article 5.5.1.2 for more detail.).

Duct Stack—A vertical group of tendons in which the space between individual tendons is less than 1.5 in.

Edge Distance—The minimum distance between the centerline of reinforcement or other embedded elements and the edge of the concrete.

Effective Depth—The depth of a component effective in resisting flexural or shear forces.

Effective Prestress—The stress or force remaining in the prestressing steel after all losses have occurred.

Embedment Length—The length of reinforcement or anchor provided beyond a critical section over which transfer of force between concrete and reinforcement may occur.

Expansion Anchor—A post-installed anchor, inserted into hardened concrete, that transfers loads to or from the concrete by direct bearing or friction or both. Expansion anchors may be torque-controlled, where the expansion is achieved by a torque acting on the screw or bolt; or displacement-controlled, where the expansion is achieved by impact forces acting on a sleeve or plug and the expansion is controlled by the length of travel of the sleeve or plug.

External Tendon—A post-tensioning tendon placed outside of the body of concrete, usually inside a box girder.

Extreme Tension Steel—The prestressed or nonprestressed reinforcement that is farthest from the extreme compression fiber.

Five Percent Fractile—A statistical term meaning 90 percent confidence that there is 95 percent probability of the actual strength exceeding the nominal strength.

Flexible Duct—A loosely interlocked duct that can be coiled into a 4.0-ft diameter without damage.

General Zone—Region adjacent to a post-tensioned anchorage within which the prestressing force spreads out to an essentially linear stress distribution over the cross-section of the component.

Hoop—Transverse reinforcement that is circular in shape with closure made using a full-welded splice, a full-mechanical coupler, or by overlapping with hooks around longitudinal reinforcement.

Intermediate Anchorage—Anchorage not located at the end surface of a member or segment for tendons that do not extend over the entire length of the member or segment; usually in the form of embedded anchors, blisters, ribs, or recess pockets.

Indirect Loading/Supporting—Application of a load or use of a support internally such as girders framing into an integral bent (pier) cap, dapped or spliced-girders where load transfer is between the top and bottom face of the member, or utility loads hung from the web of a girder.

Internal Tendon—A post-tensioning tendon placed within the body of concrete.

Isotropic Reinforcement—An arrangement of reinforcement in which the bars are orthogonal, and the reinforcement ratios in the two directions are equal.

Jacking Force—The force exerted by the device that introduces tension into the tendons.

Launching Bearing—Temporary bearings with low friction characteristics used for construction of bridges by the incremental launching method.

Launching Nose—Temporary steel assembly attached to the front of an incrementally launched bridge to reduce superstructure force effects during launching.

Lightweight Concrete—Concrete containing lightweight aggregate conforming to AASHTO M 195 and having an equilibrium density not exceeding 0.135 kcf, as determined by ASTM C567/C567M.

Local Bending—The lateral flexural bending caused by curved post-tensioning tendons on the concrete cover between the internal ducts and the inside face of the curved element (usually webs).

Local Shear—The lateral shear caused by curved post-tensioning tendons on the concrete cover between the internal ducts and the inside face of the curved element (usually webs).

Local Zone—The volume of concrete that surrounds and is immediately ahead of the anchorage device and that is subjected to high compressive stresses.

Low Relaxation Steel—Prestressing strand in which the steel relaxation losses have been substantially reduced by stretching at an elevated temperature.

Maturity of Concrete—Duration of time between time of loading and the time being considered for creep effects or duration of time between the end of concrete curing and the time being considered for shrinkage effects.

Net Tensile Strain—The tensile strain at nominal resistance exclusive of strains due to effective prestress, creep, shrinkage, and temperature.

Normal Weight Concrete—Plain concrete having an equilibrium density greater than 0.135 kcf and a density not exceeding 0.155 kcf.

Post-Installed Anchor—An anchor installed in hardened concrete. Expansion, undercut, and adhesive anchors are examples of post-installed anchors.

Post-Tensioning—A method of prestressing in which the tendons are tensioned after the concrete has reached a predetermined strength.

Post-Tensioning Duct—A form device used to provide a path for post-tensioning tendons or bars in hardened concrete.

Precast Members—Concrete elements cast in a location other than their final position.

Precompressed Tensile Zone—Any region of a prestressed component in which prestressing causes compressive stresses and service load effects cause tensile stresses.

Prestressed Concrete—Concrete components in which stresses and deformations are introduced by application of prestressing forces.

Pretensioning—A method of prestressing in which the strands are tensioned before the concrete is placed.

Regional Bending—Transverse bending of a concrete box girder web due to concentrated lateral prestress forces resisted by the frame action of the box acting as a whole.

Reinforced Concrete—Structural concrete containing no less than the minimum amounts of prestressing tendons or nonprestressed reinforcement specified herein.

Reinforcement—Reinforcing bars, welded wire reinforcement, and/or prestressing steel.

Relaxation—The time-dependent reduction of stress in prestressing tendons.

Resal Effect—The reduction or addition of shear based on the bottom slab compression angle with the center of gravity.

Rigid Duct—Seamless tubing stiff enough to limit the deflection of a 20.0-ft length supported at its ends to not more than 1.0 in.

Segmental Construction—The fabrication and erection of a structural element (superstructure and/or substructure) using individual elements, which may be either precast or cast-in-place. The completed structural element acts as a monolithic unit under some or all design loads. Post-tensioning is typically used to connect the individual elements. For superstructures, the individual elements are typically short (with respect to the span length), box-shaped segments with monolithic flanges that comprise the full width of the structure. (See Article 5.12.5.)

Semirigid Duct—A corrugated duct of metal or plastic sufficiently stiff to be regarded as not coilable into conventional shipping coils without damage.

Shielded Strand—See *Debonded Strand*.

Slab—A component having a width of at least four times its effective depth.

Special Anchorage Device—Anchorage device whose adequacy should be proven in a standardized acceptance test. Most multiplane anchorages and all bond anchorages are special anchorage devices.

Specified Concrete Strength—The compressive strength of concrete specified in the contract documents which may be greater than the compressive strength of concrete for use in design, f'_c .

Spiral—Continuously wound bar or wire in the form of a cylindrical helix.

Spliced Precast Girder—A type of superstructure in which precast concrete beam-type elements are joined longitudinally, typically using post-tensioning, to form the completed girder. The bridge cross-section is typically a conventional structure consisting of multiple precast girders. This type of construction is not considered to be segmental construction for the purposes of these Specifications. (See Article 5.12.3.4.)

Splitting Tensile Strength—The tensile strength of concrete that is determined by a splitting test made in accordance with AASHTO T 198 (ASTM C496/C496M).

Stress Range—The algebraic difference between the maximum and minimum stresses due to transient loads.

Structural Concrete—All concrete used for structural purposes.

Structural Mass Concrete—Any large volume of concrete where special materials or procedures are required to cope with the generation of heat of hydration and attendant volume change to minimize cracking.

Strut-and-Tie Method (STM)—A procedure used principally in regions of concentrated forces and geometric discontinuities to determine concrete proportions and reinforcement quantities and patterns based on an analytic

model consisting of compression struts in the concrete, tensile ties in the reinforcement, and the geometry of nodes at their points of intersection.

Supplementary Anchor Reinforcement—Reinforcement that acts to restrain the potential concrete breakout but is not designed to transfer the full design load from the anchors into the structural member.

Temperature Gradient—Variation of temperature of the concrete over the cross-section.

Temporary Stress—Stress that occurs for a limited duration during preservice conditions.

Tendon—A high-strength steel element used to prestress the concrete.

Tension-Controlled Section—A cross-section in which the net tensile strain in the extreme tension steel at nominal resistance is greater than or equal to the tension-controlled strain limit.

Tension-Controlled Strain Limit—The net tensile strain in the extreme tension steel at nominal resistance. (See Article 5.6.2.1.)

Tie—For compression members, ties are transverse reinforcement enclosing longitudinal reinforcement. A tie is made up of one or several reinforcement elements generally rectangular, semi-circular, or polygonal in shape, without reentrant corners, with closure made using a full-welded splice, a full-mechanical coupler, bar lapping, or hooks around longitudinal reinforcement. In other members, a tie refers to bar reinforcement used to restrain other reinforcement or prestressing ducts. A tie also refers to a tension element in a strut-and-tie model.

Transfer—The operation of imparting the force in a pretensioning anchoring device to the concrete.

Transfer Length—The length over which the pretensioning force is transferred to the concrete by bond and friction in a pretensioned member.

Transverse Reinforcement—Reinforcement used to resist shear, torsion, and lateral forces or to confine concrete in a structural member. The terms “stirrups” and “web reinforcement” are usually applied to transverse reinforcement in flexural members and the terms “ties,” “cross-ties,” “hoops,” and “spirals” are applied to transverse reinforcement in compression members.

Unbonded Tendon—Tendons that are effectively bonded at only their anchorages and intermediate bonded sections, such as deviators.

Undercut Anchor—A post-installed anchor that develops its tensile strength from the mechanical interlock provided by undercutting of the concrete at the embedded end of the anchor. The undercutting is achieved with a special drill before installing the anchor or alternatively by the anchor itself during its installation.

Volume Change Effects—Stresses and deformations in a reinforced or prestressed concrete member caused by shrinkage and creep of concrete and thermal expansion or contraction.

Wobble Friction—The friction caused by the deviation of a tendon duct or sheath from its specified profile.

Yield Strength—The specified yield strength of reinforcement.

5.3—NOTATION

A	=	maximum area of the portion of the supporting surface that is similar to the loaded area and concentric with it and that does not overlap similar areas for adjacent anchorage devices (in. ²); for segmental construction: static weight of precast segment being handled for precast cantilever construction or the empty weight of the form-traveler being utilized for cast-in-place cantilever construction (kip) (5.8.4.4.2) (5.12.5.3.2)
A_b	=	effective net area of a bearing plate (in. ²); effective bearing area (in. ²); area of a single bar (in. ²) (5.8.4.4.2) (5.8.4.5.2) (5.10.8.2.6d)
A_{br}	=	cross-sectional area of an individual transverse bar crossing the potential plane of splitting (in. ²) (C5.10.8.2.1c)

A_c	=	area of core measured to the outside of the transverse reinforcement (in. ²); area of section calculated using the gross composite concrete section properties of the girder and the deck and the deck-to-girder modular ratio (in. ²); area of column core measured to the outside of the transverse reinforcement (in. ²); gross area of concrete deck slab (in. ²) (5.6.4.6) (5.9.3.4.3a) (5.11.4.1.4) (C5.12.3.3.3)
A_{cb}	=	the area of the continuing cross-section within the extensions of the sides of the anchor plate or blister, i.e., the area of the blister or rib shall not be taken as part of the cross-section (in. ²) (5.9.5.6.7b)
A_{conf}	=	bearing area of confined concrete in the local zone (in. ²) (5.8.4.5.2)
A_{cp}	=	area enclosed by outside perimeter of concrete cross-section (in. ²) (5.7.2.1)
A_{ct}	=	area of concrete on the flexural tension side of the member (5.7.3.4.2) (CB5.2) (in. ²)
A_{cv}	=	area of concrete considered to be engaged in interface shear transfer (in. ²) (5.7.4.2)
A_d	=	area of deck concrete (in. ²) (5.9.3.4.3d)
A_g	=	gross area of section (in. ²); gross area of bearing plate (in. ²) (5.6.4.2) (5.8.4.4.2)
A_h	=	total area of horizontal crack control reinforcement within spacing s_h (in. ²); area of shear reinforcement parallel to flexural tension reinforcement (in. ²) (5.8.2.6) (5.8.4.2.1)
A_{hr}	=	area of one leg of hanger reinforcement in beam ledges and inverted T-beams (in. ²) (5.8.4.3.5)
AI	=	dynamic response due to accidental release or application of a precast segment load, empty form-traveler load, or other sudden application of an otherwise static load to be added to the dead load; in lieu of a dynamic analysis, may also be taken as 100 percent of load A (kip) (5.12.5.3.2)
A_t	=	total area of longitudinal torsion reinforcement in a box girder (in. ²); area of longitudinal column reinforcement (in. ²) (5.7.3.6.3) (5.10.8.4.2a)
A_n	=	area of reinforcement in bracket or corbel resisting tensile force N_{uc} (in. ²) (5.8.4.2.2)
A_o	=	area enclosed by shear flow path, including any area of holes therein (in. ²) (5.7.2.1)
A_{plate}	=	area of anchor bearing plate (5.8.4.5.2)
A_{ps}	=	area of prestressing steel (in. ²); area of prestressing steel on the flexural tension side of the member (in. ²) (5.4.6.3) (5.7.3.4.2)
A_{psb}	=	area of bonded prestressing steel (in. ²) (5.6.3.1.3b)
A_{psu}	=	area of unbonded prestressing steel (in. ²) (5.6.3.1.3b)
A_s	=	area of nonprestressed tension reinforcement (in. ²); area of nonprestressed steel on the flexural tension side of the member at the section under consideration (in. ²); total area of reinforcement located within the distance $h/4$ from the end of the beam (in. ²); area of tie reinforcement (in. ²); area of reinforcement in each direction and each face (in. ² /ft); total area of longitudinal deck reinforcement (in. ²); area of reinforcement in the design width (in. ²) (5.6.3.1.1) (5.7.3.4.2) (5.9.4.4.1) (5.9.4.4.3) (5.10.6) (C5.12.3.3.3) (5.12.7.3)
A_{sb}	=	area of required reinforcement due to transverse bending for one face of a web or flange within a distance, s (in. ²) (C5.12.5.3.8d)
A'_s	=	area of compression reinforcement (in. ²) (5.6.3.1.1)
A_{sh}	=	total cross-sectional area of tie reinforcement, including supplementary cross-ties having a vertical spacing of s and crossing a section having a core dimension of h_c (in. ²) (5.11.4.1.4)
A_{sk}	=	area of skin reinforcement per unit height on each side face (in. ²) (5.6.7)
A_{sp}	=	cross-sectional area of spiral or hoop (in. ²); area of shaft spiral or hoop (in. ²) (5.6.4.6) (5.10.8.4.2a)
A_{sp1}	=	cross-sectional area of a tendon in the larger group (in. ²) (C5.9.3.2.3b)
A_{sp2}	=	cross-sectional area of a tendon in the smaller group (in. ²) (C5.9.3.2.3b)
A_{st}	=	total area of longitudinal nonprestressed reinforcement (in. ²); area of required torsion reinforcement for one face of an exterior web or flange within a distance s (in. ²) (5.6.4.4) (C5.12.5.3.8d)
A_{sv}	=	area of required shear reinforcement for one face of a web within a distance s (in. ²) (C5.12.5.3.8d)
A_{s-BW}	=	area of steel in the band width (in. ²) (5.12.8.5)
A_{s-SD}	=	total area of steel in short direction (in. ²) (5.12.8.5)
A_t	=	area of one leg of closed transverse torsion reinforcement in solid members, or total area of transverse torsion reinforcement in the exterior web and flange of hollow members (in. ²); total area of transverse torsion reinforcing in the exterior web and flange (in. ²) (5.7.3.6.2) (5.12.5.3.8d)
A_{tr}	=	total cross-sectional area of all transverse reinforcement that is within the spacing s and that crosses the potential plane of splitting through the reinforcement being developed (in. ²); area of concrete deck slab with transformed longitudinal deck reinforcement (in. ²) (5.10.8.2.1c) (C5.12.3.3.3)
A_v	=	area of a transverse reinforcement within distance s (in. ²); total area of vertical crack control reinforcement within spacing s_v (in. ²) total area of transverse reinforcement in all webs in the cross-section within a distance s (in. ²) (5.7.2.5) (5.8.2.6) (5.12.5.3.8c)

A_{vf}	=	area of interface shear reinforcement crossing the shear plane within the area A_{cv} (in. ²); area of shear-friction reinforcement (in. ²); total area of reinforcement, including flexural reinforcement (in. ²) (5.7.4.2) (5.8.4.2.2) (5.11.4.4)
A_w	=	area of an individual wire to be developed or spliced (in. ²) (5.10.8.2.5)
A_1	=	area under bearing device (in. ²) (5.6.5)
A_2	=	Notional area of the lower base of the largest frustum of a pyramid, cone, or tapered wedge contained wholly within the support and having for its upper base the loaded area and having side slopes of 1 vertical to 2 horizontal (in. ²) (5.6.5)
a	=	depth of equivalent rectangular stress block (in.); shear span (in.); lateral dimension of the anchorage device or group of devices in the direction considered (in.); lateral dimension of the anchorage device or group of devices in the transverse direction of the slab (in.) (5.6.3.2.2) (C5.8.2.2) (5.8.4.5.3) (5.8.4.5.5)
a_{eff}	=	lateral dimension of the effective bearing area of the anchorage measured parallel to the larger dimension of the cross-section (in.) (5.8.4.5.2)
a_f	=	distance from centerline of girder reaction to vertical reinforcement in backwall or stem of inverted T (in. ²) (5.8.4.3)
a_v	=	distance from face of wall to the concentrated load (in.) (5.8.4.2.1)
B_w	=	total web width in single cell or symmetrical two-cell hollow sections at height of the web where principal tension is being checked (in.) (5.9.2.3.3)
b	=	width of the compression face of the member (in.); for a flange section in compression, the effective width of the flange as specified in Article 4.6.2.6 (in.); width of corbel or ledge (in.); least width of component section (in.); width of a pier (in.); design width (in.) (5.6.3.1.1) (5.6.3.5.2b) (5.8.4.2.2) (5.10.6) (5.11.4.2) (5.12.7.3)
b_b	=	width of bearing (in.) (5.9.4.4.3)
b_e	=	effective width of the shear flow path, to be taken as the minimum thickness of the exterior webs or flanges comprising the closed box section (in.); the effective thickness of the shear flow path of the elements making up the space truss model resisting torsion (in.) (5.7.2.1) (5.12.5.3.8c)
b_{eff}	=	lateral dimension of the effective bearing area measured parallel to the smaller dimension of the cross-section (in.) (5.8.4.5.2)
b_f	=	the overall width of the inverted T-beam flange and bottom flange of the I-beam (in.) (5.8.4.3.5) (5.9.4.3.3)
b_o	=	the perimeter of critical section for shear (in.) (5.8.4.3.4)
b_v	=	width of web adjusted for the presence of ducts (in.); effective web width taken as the minimum web width, measured parallel to the neutral axis, between the resultants of the tensile and compressive forces due to flexure, or for circular sections, the diameter of the section, modified for the presence of ducts where applicable (in.) For grouted ducts, no modification is necessary. For ungrouted ducts, reduce b_v by the diameter of the duct.; effective web width taken as the minimum web width within the depth d_v (in.); effective web width taken as the total minimum width of all webs in the cross-section within the depth d_v adjusted for the effect of openings or ducts (in.) (5.7.2.5) (5.7.2.8) (5.7.3.3) (5.12.5.3.8c)
b_{vi}	=	interface width considered to be engaged in shear transfer (in.) (5.7.4.3)
b_w	=	web width or diameter of a circular section (in.); gross width of web, not reduced for the presence of post-tensioning ducts (in.); width of member's web (in.); the width of the inverted T-beam stem (in.); web width at the height of the web where principal tension is being checked (in.); web width of I-beam (in.) (5.6.3.1.1) (C5.8.2.2) (5.8.4.3.4) (5.9.2.3.3)
CEQ	=	for segmental construction: specialized construction equipment (kip) (5.12.5.3.2)
CLE	=	for segmental construction: longitudinal construction equipment load (kip) (5.12.5.3.2)
CLL	=	for segmental construction: distributed construction live load (ksf) (5.12.5.3.2)
CR	=	creep effects (ksi) (5.12.5.3.2)
C_1	=	compression force above the shear plane associated with M_1 (kip) (C5.7.4.5)
C_{u2}	=	compression force above the shear plane associated with M_{u2} (kip) (C5.7.4.5)
c	=	distance from the extreme compression fiber to the neutral axis (in.); cohesion factor (ksi); spacing from centerline of bearing to end of beam ledge (in.); required concrete cover over the confining reinforcement (in.) (5.6.2.1) (5.7.4.3) (5.8.4.3.2) (C5.8.4.4.1)
c_b	=	distance from the bearing reaction force on either side of the girder to the girder centerline; the smaller of distance from center of bar or wire being developed to the nearest concrete surface and one-half the center-to-center spacing of the bars or wires being developed (in.) (5.9.4.4.3) (5.10.8.2.1c)
D	=	external diameter of the circular member (in.); diameter of circular bearing pad (in.) (C5.7.2.8) (5.8.4.3.4)
DC	=	weight of supported structure (kip) (5.12.5.3.2)
$DIFF$	=	for segmental construction: differential load (kip) (5.12.5.3.2)

D_r	=	diameter of the circle passing through the centers of the longitudinal reinforcement (in.) (C5.7.2.8)
DW	=	superimposed dead load (kip) or (klf) (5.12.5.3.2)
d	=	effective depth of the member defined as the distance between the extreme compression fiber and the centroid of the primary longitudinal reinforcement (in.); depth of a pier (in.); $0.8h$ or the distance from the extreme compression fiber to the centroid of the prestressing reinforcement, whichever is greater (in.) (5.5.1.2.1) (5.11.4.2) (5.12.5.3.8c)
d_b	=	nominal strand diameter (in.); nominal diameter of reinforcing bar (in.); nominal diameter of reinforcing bar or wire (in.) (5.9.4.3.2) (5.10.2.1) (5.10.8.2.1a)
d_{burst}	=	distance from anchorage device to the centroid of the bursting force, T_{burst} (in.) (5.8.4.5.3)
d_c	=	core diameter of column measured to the outside of transverse reinforcement (in.); thickness of concrete cover measured from extreme tension fiber to center of the flexural reinforcement located closest thereto (in.); minimum concrete cover over the tendon duct (in.) (5.6.4.6) (5.6.7) (5.9.5.4.4b)
d_{duct}	=	outside diameter of post-tensioning duct (in.) (5.9.5.4.4b)
d_e	=	depth of center of gravity of steel (in.); effective depth from extreme compression fiber to the centroid of the tensile force in the tensile reinforcement (in.) (5.8.4.2.2) (5.12.5.3.8d)
d_{eff}	=	one-half the effective length of the failure plane in shear and tension for a curved element (in.) (5.9.5.4.4b)
d_f	=	distance from top of ledge to the bottom longitudinal reinforcement (in.) (5.8.4.3.4)
d_t	=	distance from the extreme compression fiber to the centroid of extreme tension steel element (in.) (5.6.7)
d_o	=	girder depth (ft) (C5.12.5.3.11c)
d_p	=	distance from extreme compression fiber to the centroid of the prestressing tendons (in.) (5.6.3.1.1)
d_s	=	distance from extreme compression fiber to the centroid of the nonprestressed tensile reinforcement measured along the centerline of the web (in.) (5.6.2.1)
d'_s	=	distance from extreme compression fiber to the centroid of compression reinforcement (in.) (5.6.3.2.2)
d_v	=	effective shear depth taken as the distance, measured perpendicular to the neutral axis, between the resultants of the tensile and compressive forces due to flexure (in.); distance between the centroid of the tension steel and the mid-thickness of the slab to compute a factored interface shear stress (in.) (5.7.2.8) (5.7.4.5)
E_b	=	modulus of elasticity of the bearing plate material (ksi) (5.8.4.4.2)
E_c	=	modulus of elasticity of concrete (ksi) (5.4.2.4)
$E_{c\ deck}$	=	modulus of elasticity of deck concrete (ksi) (5.9.3.4.3d)
E_{ct}	=	modulus of elasticity of concrete at transfer (ksi) (C5.9.3.2.3a)
E_{ct}	=	modulus of elasticity of concrete at transfer or time of load application (ksi) (5.9.3.2.3a)
E_{eff}	=	effective modulus of elasticity (ksi) (C5.12.5.3.6)
EI	=	flexural stiffness (kip-in. ²) (5.6.4.3)
E_p	=	modulus of elasticity of prestressing steel (ksi) (5.6.4.4)
E_s	=	modulus of elasticity of steel reinforcement (ksi); modulus of elasticity of longitudinal steel (ksi) (5.4.3.2) (5.6.4.3)
e	=	minimum edge distance for anchorage devices as specified by the supplier (in.); eccentricity of the anchorage device or group of devices with respect to the centroid of the cross-section, always taken as positive (in.); base of natural logarithms (C5.8.4.4.1) (5.8.4.5.3) (5.9.2.1)
e_d	=	eccentricity of deck with respect to the gross composite section (in.) (5.9.3.4.3d)
e_m	=	average prestressing steel eccentricity at midspan (in.) (C5.9.3.2.3a)
e_{pc}	=	eccentricity of prestressing force with respect to centroid of composite section (in.) (5.9.3.4.3a)
e_{pg}	=	eccentricity of prestressing force with respect to centroid of girder (in.) (5.9.3.4.2a)
F	=	force effect determined using the modulus of elasticity of the concrete at the time loading is applied (kip) (5.9.2.1)
F'	=	reduced force effect (kip) (5.9.2.1)
F_h	=	force developed by hooks or heads (kip) (5.10.8.2.1a)
F_{u-in}	=	in-plane deviation force effect per unit length of tendon (kips/ft) (5.9.5.4.4a)
F_{u-out}	=	out-of-plane force effect per unit length of tendon (kips/ft) (5.9.5.4.5)
f_b	=	bearing stress equal to the factored tendon force divided by the effective net area of the bearing plate (ksi) (5.8.4.4.2)
f'_c	=	compressive strength of concrete for use in design (ksi) (5.4.2.1)
f_{ca}	=	concrete compressive stress ahead of the anchorage devices (ksi) (5.8.4.5.2)
f_{cb}	=	unfactored minimum compressive stress in the region behind the anchor at service limit states and any stage of construction (ksi) (5.9.5.6.7b)
f_{cgp}	=	concrete stress at the center of gravity of prestressing tendons due to the prestressing force immediately at transfer and the self-weight of the member at the section of maximum moment (ksi) (5.9.3.2.3a)

f'_{ci}	= design concrete compressive strength at time of prestressing for pretensioned members and at time of initial loading for nonprestressed members (ksi); design concrete strength at time of application of tendon force (ksi) (5.4.2.3.2) (5.8.4.4.2)
f_{cpe}	= compressive stress in concrete due to effective prestress forces only (after allowance for all prestress losses) at extreme fiber of section where tensile stress is caused by externally applied loads (ksi) (5.6.3.3)
f_{cr}	= design flexural cracking stress of the hypothetical unreinforced concrete beam consisting of the cover concrete over the inside face of a stack of horizontally curved post-tensioned tendons (ksi) (5.9.5.4.4c)
f_{ct}	= average splitting tensile strength of concrete (ksi) (5.4.2.8)
f_{cu}	= limiting compressive stress at the face of a node (ksi) (5.8.2.5.1)
f_{max}	= maximum principal stress in the web, compression positive (ksi) (C5.9.2.3.3)
f_{min}	= minimum live-load stress resulting from the Fatigue I load combination, combined with the more severe stress from either the unfactored permanent loads or the unfactored permanent loads, shrinkage, and creep-induced external loads (ksi); minimum principal stress in the web, tension negative (ksi) (5.5.3.2) (5.9.2.3.3)
f_n	= nominal concrete bearing stress (ksi) (5.8.4.4.2)
f_{pbt}	= stress in prestressing steel immediately prior to transfer (ksi) (C5.9.3.2.3a)
f_{pc}	= unfactored compressive stress in concrete after prestress losses have occurred either at the centroid of the cross-section resisting transient loads or at the junction of the web and flange where the centroid lies in the flange (ksi) (5.7.2.1)
f_{pcx}	= horizontal stress in the web (ksi) (5.9.2.3.3)
f_{pcy}	= vertical stress in the web (ksi) (5.9.2.3.3)
f_{pe}	= effective stress in prestressing steel (ksi) (5.6.3.1.2)
f_{pi}	= prestressing steel stress immediately prior to transfer (ksi) (5.9.3.3)
f_{po}	= a parameter taken as modulus of elasticity of prestressing tendons multiplied by the locked-in difference in strain between the prestressing tendons and the surrounding concrete (ksi) (5.7.3.4.2)
f_{ps}	= average stress in prestressing steel at the time for which the nominal resistance of member is required (ksi) (5.6.3.1)
f_{pt}	= stress in prestressing strands immediately after transfer (ksi) (5.9.3.4.2c)
f_{pu}	= specified tensile strength of prestressing steel (ksi) (5.4.4.1) (5.4.6.3)
f_{px}	= design stress in pretensioned strand at nominal flexural strength at section of member under consideration (ksi) (5.9.4.3.2)
f_{py}	= yield strength of prestressing steel (ksi) (5.4.4.1)
f_r	= modulus of rupture of concrete (ksi) (5.4.2.6)
f_s	= stress in the nonprestressed tension reinforcement at nominal flexural resistance (ksi); stress in steel (ksi) (5.6.3.1.1) (5.9.4.4.1)
f'_s	= stress in the nonprestressed compression reinforcement at nominal flexural resistance (ksi) (5.6.3.1.1)
f_{ss}	= calculated tensile stress in nonprestressed reinforcement at the service limit state not to exceed $0.60 f_y$ (ksi) (5.6.7)
f_{ut}	= specified minimum tensile strength of column longitudinal reinforcement (ksi), 90 ksi for ASTM A615/A615M and 80 ksi for ASTM A706/A706M (5.10.8.4.2a)
f_y	= specified minimum yield strength of reinforcement (ksi), note that limits on physical yield strength or on substitution limits in equations may be specified in various articles (5.5.3.2) (5.9.4.4.3) (5.10.6) (Appendix D5)
f_{ytr}	= specified minimum yield strength of shaft transverse reinforcement (ksi) (5.10.8.4.2a)
f'_y	= specified minimum yield strength of compression reinforcement (ksi) (5.6.2.1)
f_{yh}	= specified minimum yield strength of transverse reinforcement (ksi) (5.6.4.6)
H	= average annual ambient relative humidity (percent) (5.4.2.3.2)
h	= overall thickness or depth of a member (in.); lateral dimension of the cross-section in the direction considered (in.); overall dimension of precast member in the direction in which splitting resistance is being evaluated (in.); least thickness of component section (in.) (5.6.7) (5.8.4.5.3) (5.9.4.4.1) (5.10.6)
h_a	= length of the back face of an STM node (in.) (5.8.2.2)
h_b	= depth of bottom bulb (in.) (5.9.4.4.3)
h_c	= span of the web between the top and bottom slabs measured along the axis of the web (in.); core dimension of tied column in direction under consideration (in.) (5.9.5.4.4d) (5.11.4.1.4)
h_{ds}	= height of the duct stack (in.) (5.9.5.4.4c)
h_f	= compression flange depth (in.); compression flange depth of an I- or T-member (in.) (5.6.3.1.1) (5.6.3.2.2)

h_{STM}	=	node-to-node depth of an STM (C5.8.2.2)
h_1	=	largest lateral dimension of member (in.) (C5.9.5.6.5b)
h_2	=	least lateral dimension of member (in.) (C5.9.5.6.5b)
I_c	=	moment of inertia of section calculated using the gross composite concrete section properties of the girder and the deck and the deck-to-girder modular ratio at service (in. ⁴) (5.9.3.4.3a)
I_{cr}	=	moment of inertia of the cracked section, transformed to concrete (in. ⁴) (5.6.3.5.2a)
IE	=	for segmental construction: dynamic load from equipment (kip) (5.12.5.3.2)
I_e	=	effective moment of inertia (in. ⁴) (5.6.3.5.2a)
I_g	=	moment of inertia of the gross concrete section about the centroidal axis, neglecting the reinforcement (in. ⁴) (5.6.3.5.2a)
I_s	=	moment of inertia of the longitudinal reinforcement about the centroidal axis (in. ⁴) (5.6.4.3)
K	=	effective length factor for compression members; wobble friction coefficient (per ft of tendon) (5.6.4.1) (5.9.3.2.2b)
K_{df}	=	transformed section coefficient that accounts for time-dependent interaction between concrete and bonded steel in the section being considered for time period between deck placement and final time (5.9.3.4.3a)
K_{id}	=	transformed section coefficient that accounts for time-dependent interaction between concrete and bonded steel in the section being considered for time period between transfer and deck placement (5.9.3.4.2a)
K_L	=	factor accounting for type of steel taken as 30 for low relaxation strands and 7 for other prestressing steel, unless more accurate manufacturer's data are available (5.9.3.4.2c)
K'_L	=	factor accounting for type of steel equal to 45 for low relaxation steel (C5.9.3.4.2c)
K_1	=	correction factor for source of aggregate taken as 1.0 unless determined by physical test, and as approved by the Owner; fraction of concrete strength available to resist interface shear (5.4.2.4) (5.7.4.3)
K_2	=	limiting interface shear resistance (5.7.4.3)
k	=	factor representing the ratio of column tensile reinforcement to total column reinforcement at the nominal resistance (5.10.8.4.2a)
k_c	=	factor for the effect of the volume-to-surface ratio for creep; ratio of the maximum concrete compressive stress to the design compressive strength of concrete (C5.4.2.3.2) (5.6.4.4)
k_f	=	factor for the effect of concrete strength (5.4.2.3.2)
k_{hc}	=	humidity factor for creep (5.4.2.3.2)
k_{hs}	=	humidity factor for shrinkage (5.4.2.3.3)
k_s	=	factor for the effect of the volume-to-surface ratio of the component (5.4.2.3.2)
k_{td}	=	time development factor (5.4.2.3.2)
k_{tr}	=	transverse reinforcement index (5.10.8.2.1c)
L	=	length of bearing pad (in.); span length (ft); span length between supports (ft) (5.8.4.3.4) (5.12.2.1) (C5.12.5.3.11c)
L_{CLR}	=	clear span between supports (in.) (5.10.8.1.2a)
L_{vi}	=	interface length considered to be engaged in shear transfer (in.) (5.7.4.3)
ℓ_a	=	effective length of a CTT node (in.); embedment length beyond the center of a support or at point of inflection (in.) (5.8.2.2) (C5.10.8.1.2b)
ℓ_b	=	length of the bearing face (in.) (5.8.2.2)
ℓ_c	=	longitudinal extent of confining reinforcement of the local zone but not more than the larger of $1.15 a_{eff}$ or $1.15 b_{eff}$ (in.); length of lap for compression lap splices (in.) (5.8.4.5.2) (5.10.8.4.5a)
ℓ_d	=	development length (in.) (5.9.4.3.2)
ℓ_{db}	=	basic development length for straight reinforcement to which modification factors are applied to determine ℓ_d (in.) (5.10.8.2.1a)
ℓ_{dh}	=	modified development length (in.) (5.10.8.2.4a)
ℓ_e	=	effective tendon length (in.); embedment length between midheight of the member and the outside end of the hook (in.) (5.6.3.1.2) (5.10.8.2.6b)
ℓ_{hb}	=	basic development length of standard hook in tension (in.) (5.10.8.2.4a)
ℓ_i	=	length of tendon between anchorages (in.) (5.6.3.1.2)
ℓ_{px}	=	distance from free end of pretensioned strand to section of member under consideration (in.) (5.9.4.3.2)
ℓ_s	=	required tension lap splice length of the column longitudinal reinforcement (in.) (5.10.8.4.2a)
ℓ_u	=	unbraced length (in.) (5.6.4.1)
M_d	=	maximum moment in a component due to service loads at the stage for which deformation is computed (kip-in.) (5.6.3.5.2a)
M_c	=	magnified factored moment (kip-in.) (5.6.4.3)
M_{cr}	=	cracking moment (kip-in.) (5.6.3.3) (5.6.3.5.2a)

M_{deck}	=	deck self-weight moment at the face of the diaphragm computed as if the bridge were continuous at the time of loading (kip-in.) (C5.12.3.3.2)
M_{dnc}	=	total unfactored dead load moment acting on the monolithic or noncomposite section (kip-in.) (5.6.3.3)
M_{end}	=	moment at the ends of a hypothetical unreinforced concrete beam consisting of the cover concrete over the inside face of a stack of horizontally curved post-tensioned tendons (kip-in.) (5.9.5.4.4c)
M_g	=	midspan moment due to member self-weight (kip-in.) (C5.9.3.2.3a)
M_{girder}	=	girder self-weight moment at the face of the diaphragm computed as if the bridge were continuous at the time of loading (kip-in.) (C5.12.3.3.2)
M_{mid}	=	moment at the midpoint of a hypothetical unreinforced concrete beam consisting of the cover concrete over the inside face of a stack of horizontally curved post-tensioned tendons (kip-in.) (5.9.5.4.4c)
M_n	=	nominal flexural resistance (kip-in.) (5.6.3.2.1)
M_{ps}	=	prestressing moment at the face of the diaphragm computed as if the bridge were continuous at the time of loading (kip-in.) (C5.12.3.3.2)
M_r	=	factored flexural resistance (kip-in.) (5.6.3.2.1)
M_{rc}	=	restraint moment due to creep (kip-in.) (C5.12.3.3.2)
M_{res}	=	total superstructure restraint moment due volume change effects (kip-in.) (C5.12.3.3.2)
M_{rx}	=	uniaxial factored flexural resistance of a section in the direction of the x -axis (kip-in.) (5.6.4.5)
M_{ry}	=	uniaxial factored flexural resistance of a section in the direction of the y -axis (kip-in.) (5.6.4.5)
M_{sh}	=	superstructure restraint moment at the face of the diaphragm due to deck shrinkage (kip-in.) (C5.12.3.3.2)
M_{sidl}	=	moment at the face of the diaphragm due to permanent loads occurring after continuity is attained (kip-in.) (C5.12.3.3.2)
M_{tg}	=	superstructure restraint moment at the face of the diaphragm due to temperature gradient (kip-in.) (C5.12.3.3.2)
M_u	=	factored moment at the section (kip-in.) (5.7.3.4.2)
M_{ux}	=	factored applied moment about the x -axis (kip-in.) (5.6.4.5)
M_{uy}	=	factored applied moment about the y -axis (kip-in.) (5.6.4.5)
M_{u2}	=	maximum factored moment at section 2 (kip-in.) (C5.7.4.5)
M_1	=	smaller end moment at the strength limit state due to factored loads acting on a compression member; positive if the member is bent in single curvature and negative if bent in double curvature (kip-in.); factored moment at section 1 concurrent with M_{u2} (5.6.4.3) (C5.7.4.5)
M_2	=	larger end moment at the strength limit state due to factored loads acting on a compression member; always positive (kip-in.) (5.6.4.3)
m	=	confinement modification factor (5.6.5)
N	=	total cycles of loading; number of identical prestressing tendons (5.5.3.4) (5.9.3.2.3b)
N_s	=	number of support hinges crossed by the tendon between anchorages or discretely bonded points (5.6.3.1.2)
N_u	=	factored axial force, taken as positive if tensile and negative if compressive (kip) (5.7.3.4.2)
N_{uc}	=	factored axial force normal to the cross-section, occurring simultaneously with V_u ; taken to be positive for tension and negative for compression; includes effects of tension due to creep and shrinkage (kip) (5.8.4.2.1)
N_w	=	total number of bonded strands at section (5.9.4.4.3)
N_1	=	number of tendons in the larger group (C5.9.3.2.3b)
N_2	=	number of tendons in the smaller group (C5.9.3.2.3b)
n	=	modular ratio = E_s/E_c or E_p/E_c ; projection of bearing plate beyond the wedge hole or wedge plate, as appropriate (in.); number of anchorages in a row; number of bars or wires developed along plane of splitting; modular ratio between deck concrete and reinforcement (5.6.1) (5.8.4.4.2) (5.8.4.5.2) (5.10.8.2.1c) (C5.12.3.3.3)
n_f	=	number of bonded strands in one side of outer portion of web (5.9.4.4.3)
P_c	=	net compressive force due to unfactored permanent force effects, normal to the shear plane (kip) (5.7.4.3)
P_n	=	nominal axial resistance (kip); nominal bearing resistance (kip); nominal resistance of a node face or tie (kip) (5.6.4.4) (5.6.5) (5.8.2.3)
P_o	=	nominal axial resistance of a section at 0.0 eccentricity (kip) (5.6.4.5)
P_r	=	factored axial resistance; factored resistance of a node face or tie (kip); factored bearing resistance of anchorages (kip); factored splitting resistance of pretensioned anchorage zones provided by reinforcement in the end of pretensioned beams (kip) (5.6.4.4) (5.8.2.3) (5.8.4.4.2) (5.9.4.4.1)
P_{rx}	=	factored axial resistance determined on the basis that only eccentricity e_y is present (kip) (5.6.4.5)
P_{rxy}	=	factored axial resistance in biaxial flexure (kip) (5.6.4.5)

P_{ry}	=	factored axial resistance determined on the basis that only eccentricity e_x is present (kip) (5.6.4.5)
P_s	=	unfactored tendon force(s) at the anchorage (kip) (5.9.5.6.7b)
P_u	=	factored applied axial force; factored tendon force (kip); factored tendon force on an individual anchor (kip); minimum factored axial load (kip) (5.6.4.3) (5.8.4.5.2) (5.8.4.5.5) (5.11.4.4)
p_c	=	length of outside perimeter of the concrete section (in.) (5.7.2.1)
p_h	=	perimeter of the centerline of the closed transverse torsion reinforcement (in.); perimeter of the centerline of the closed transverse torsion reinforcement for solid members, or the perimeter of the centroid of the transverse torsion reinforcement in the exterior webs and flanges for hollow members (in.); perimeter of the polygon defined by the centroids of the longitudinal chords of the space truss resisting torsion (in.) (5.7.3.4.2) (5.7.3.6.3) (5.12.5.3.8d)
Q	=	unfactored force effect in associated units (5.12.5.3.4b)
Q_g	=	lesser of the first moment of gross concrete area above or below the height of the web where the principal tension is being checked (in. ³) (5.9.2.3.3)
R	=	radius of curvature of the tendon at the considered location (ft); radius of curvature of the tendon in a vertical plane at the considered location (ft) (5.9.5.4.4a) (5.9.5.4.5)
$R_{min,d}$	=	minimum tendon radius at deviation saddle (ft) (5.4.6.3)
r	=	radius of gyration of gross cross-section (in.) (5.6.4.1)
S	=	center-to-center spacing of bearing along a beam ledge (in.) (5.8.4.3.2)
S_c	=	section modulus for the extreme fiber of the composite section where tensile stress is caused by externally applied loads (in. ³) (5.6.3.3)
SH	=	shrinkage (5.12.5.3.2)
S_{max}	=	spacing of transverse shaft reinforcement (in.) (5.10.8.4.2a)
S_{nc}	=	section modulus for the extreme fiber of the monolithic or noncomposite section where tensile stress is caused by externally applied loads (in. ³) (5.6.3.3)
s	=	pitch or vertical spacing of transverse reinforcement (in.); average spacing of nonprestressed reinforcement in layer closest to tension face (in.); spacing of transverse reinforcement (in.); spacing of hanger reinforcing bars (in.); center-to-center spacing of anchorages (in.); anchorage spacing (in.); maximum center-to-center spacing of transverse reinforcement within ℓ_d (in.); spacing of stirrups (in.) (5.6.4.6) (5.6.7) (5.7.2.5) (5.8.4.3.5) (5.8.4.5.2) (5.8.4.5.5) (5.10.8.2.1c) (5.12.5.3.8c)
s_h	=	spacing of horizontal crack control reinforcement (in.) (5.8.2.6)
s_{max}	=	maximum permitted spacing of transverse reinforcement (in.) (5.7.2.6)
s_v	=	spacing of vertical crack control reinforcement (in.) (5.8.2.6)
s_w	=	spacing of wires to be developed or spliced (in.) (5.10.8.2.5)
s_x	=	crack spacing parameter (in.) (5.7.3.4.2)
s_{xe}	=	crack spacing parameter as influenced by aggregate size (in.) (5.7.3.4.2)
T	=	concurrent torsional moment for Service III load combination (kip-in.); thermal (°F); tension force in positive moment continuity reinforcement (5.9.2.3.3) (5.12.5.3.2) (C5.12.3.3.6)
T_{burst}	=	tensile force in the anchorage zone acting ahead of the anchorage device and transverse to the tendon axis (kip) (5.8.4.5.3)
T_{cr}	=	torsional cracking moment (kip-in.); axial force due to creep (kip) (5.7.2.1) (C5.12.3.3.2)
T_{ia}	=	tie-back tension force at the intermediate anchorage (kip) (5.9.5.6.7b)
T_n	=	nominal torsional resistance (kip-in.) (5.7.2.1)
T_r	=	factored torsional resistance (kip-in.) (5.7.2.1)
T_{res}	=	total restraint axial force due to volume change effects (kip) (C5.12.3.3.2)
T_{sh}	=	axial force due to deck shrinkage (kip) (C5.12.3.3.2)
T_{tg}	=	axial force due to temperature gradient (kip) (C5.12.3.3.2)
T_{tu}	=	axial force due to uniform temperature change (kip) (C5.12.3.3.2)
T_u	=	applied factored torsional moment (kip-in.); applied factored torsional moment on the girder (5.7.2.1) (5.7.3.4.2)
T_1	=	edge tension force (kip) (5.8.4.5.5)
T_2	=	bursting force (kip) (5.8.4.5.5)
t	=	maturity of concrete (day); thickness of wall (in.); average thickness of bearing plate (in.); member thickness (in.); time between strand tensioning and deck placement (day) (5.4.2.3.2) (5.6.4.7.1) (5.8.4.4.2) (5.8.4.5.2) (C5.9.3.4.2c)
t_d	=	maturity of concrete at deck placement (day) (5.9.3.4.2b) (C5.12.3.3.2)
t_f	=	final maturity of concrete (day) (5.9.3.4.2a) (C5.12.3.3.2)
t_i	=	age of concrete at time of initial load application (day); age of concrete at time of initial deck placement (day) (5.4.2.3.2) (5.9.3.4.2a) (C5.12.3.3.2)
t_w	=	web thickness (in.) (5.9.5.4.4b)

U	=	for segmental construction: segment unbalance (kip) (5.12.5.3.2)
V	=	shear force for Service III load combination (kip) (5.9.2.3.3)
V_c	=	nominal shear resistance of the concrete (kip) (5.7.2.3)
V_{hi}	=	factored interface shear force per unit length (kips/length) (C5.7.4.5)
V_n	=	nominal shear resistance (kip); nominal punching shear resistance (kip); nominal shear resistance of two shear planes per unit length (kips/in.) (5.7.2.1) (5.8.4.3.4) (5.9.5.4.4b)
V_{ni}	=	nominal interface shear resistance (kip) (5.7.2.1)
V_p	=	component of prestressing force in the direction of the shear force (kip) (5.7.2.3)
V_r	=	factored shear resistance (kip); shear resistance per unit length of the concrete cover against pullout by deviation forces (kip-in.) (5.7.2.1) (5.9.5.4.4b)
V_{ri}	=	factored interface shear resistance (kip) (5.7.4.3)
V/S	=	volume-to-surface ratio (5.4.2.3.2)
V_s	=	shear resistance provided by transverse reinforcement (kip) (5.7.3.3)
V_u	=	factored shear force (kip); factored shear force for the girder or for the web under consideration (kip); maximum factored reaction at bearing (k) (5.7.2.3) (5.7.3.4.2) (5.9.4.4.3)
V_{ui}	=	factored interface shear force due to total load based on the applicable strength and extreme event load combinations (kip); factored interface shear force for a concrete girder/slab bridge (kip/ft) (5.7.4.3) (5.7.4.5)
V_{u1}	=	maximum factored vertical shear at section 1 (kip) (5.7.4.5)
V_1	=	factored vertical shear at section 1 concurrent with M_{u2} (kip) (C5.7.4.5)
v	=	concrete efficiency factor (5.8.2.5.3a)
v_u	=	shear stress (ksi) (5.7.2.6)
W	=	width of bearing plate or pad (in.) (5.8.4.3.2)
W/CM	=	water/cementitious materials ratio designated in earlier practice as water-cement ratio (5.4.2.1)
WE	=	for segmental construction: horizontal wind load on equipment (kip) (5.12.5.3.2)
WS	=	for segmental construction: horizontal wind on structure (ksf) (5.12.5.3.2)
WUP	=	for segmental construction: wind uplift on cantilever (ksf) (5.12.5.3.2)
w_c	=	unit weight of concrete (kcf) (5.4.2.4)
X_u	=	clear length of the constant thickness portion of a wall between other walls or fillers between walls (in.) (5.6.4.7.1)
x	=	length of a prestressing tendon from the jacking end to any point under consideration (ft) (5.9.3.2.2b)
x_p	=	horizontal distance from girder centerline to centroid of bonded strands in outer portion of bulb (in.) (5.9.4.4.3)
y_p	=	vertical distance from girder soffit to centroid of bonded strands in outer portion of the bulb (in.) (5.9.4.4.3)
y_t	=	distance from the centroidal axis of the gross section to the extreme fiber in tension (in.) (5.6.3.5.2a)
α	=	angle of inclination of transverse reinforcement to longitudinal axis (degrees); fraction defining the bearing face length of a portion of a nodal region; angle of inclination of a tendon force with respect to the centerline of the member, positive for concentric tendons or if the anchor force points toward the centroid of the section, negative if the anchor force points away from the centroid of the section (degrees); total angular change of prestressing steel path from jacking end to a point under investigation (rad.) (5.7.3.3) (5.8.2.2) (5.8.4.5.3) (5.9.3.2.2b)
α_h	=	total horizontal angular change of prestressing steel path from jacking end to a point under investigation (rad.) (5.9.3.2.2b)
α_v	=	total vertical angular change of prestressing steel path from jacking end to a point under investigation (rad.) (5.9.3.2.2b)
α_1	=	stress block factor taken as the ratio of equivalent rectangular concrete compressive stress block intensity to the compressive strength of concrete used in design (5.6.2.2)
β	=	factor indicating the ability of diagonally cracked concrete to transmit tension and shear; ratio of long side to short side of footing (5.7.3.3) (5.12.8.5)
β_b	=	ratio of the area of reinforcement cutoff to the total area of tension reinforcement at the section (C5.10.8.1.2a)
β_c	=	ratio of the long side to the short side of the rectangle through which the concentrated load or reaction force is transmitted (5.12.8.6.3)
β_d	=	ratio of maximum factored permanent moments to maximum factored total load moment; always positive (5.6.4.3)
β_s	=	ratio of flexural strain at the extreme tension face to the strain at the centroid of the reinforcement layer nearest the tension face (5.6.7)

β_t	=	ratio of unfactored compressive stress due to permanent loads (taken as a negative value) transverse to the plane of splitting to the modulus of rupture, as determined by Article 5.4.2.6 ($-1 \leq \beta_t \leq 0$) (5.10.8.2.1c)
β_1	=	stress block factor taken as the ratio of the depth of the equivalent uniformly stressed compression zone assumed in the strength limit state to the depth of the actual compression zone (5.6.2.2)
γ	=	load factor (5.5.3.1)
γ_e	=	exposure factor (5.6.7)
γ_h	=	correction factor for relative humidity of the ambient air (5.9.3.3)
γ_{st}	=	correction factor for specified concrete strength at time of prestress transfer to the concrete member (5.9.3.3)
γ_1	=	flexural cracking variability factor (5.6.3.3)
γ_2	=	prestress variability factor (5.6.3.3)
γ_3	=	ratio of specified minimum yield strength to ultimate tensile strength of the nonprestressed reinforcement (5.6.3.3)
Δf	=	force effect, live load stress range due to the passage of the fatigue load (ksi) (5.5.3.1)
$(\Delta F)_{TH}$	=	constant-amplitude fatigue threshold (ksi) (5.5.3.1)
Δf_{cd}	=	change in concrete stress at centroid of prestressing strands due to long-term losses between transfer and deck placement, combined with deck weight and superimposed loads (ksi) (5.9.3.4.3b)
Δf_{cdf}	=	change in concrete stress at centroid of prestressing strands due to shrinkage of deck concrete (ksi) (5.9.3.4.3d)
Δf_{cdp}	=	change in concrete stress at center of gravity of prestressing steel due to all dead loads, except dead load acting at the time the prestressing force is applied (ksi) (5.9.3.6)
Δf_{pA}	=	loss due to anchorage set (ksi) (5.9.3.1)
Δf_{pCD}	=	change in prestress due to creep of girder concrete between time of deck placement and final time (ksi) (5.9.3.4.1)
Δf_{pCR}	=	prestress loss due to creep of girder concrete between transfer and deck placement (ksi) (5.9.3.4.1)
Δf_{pES}	=	sum of all losses or gains due to elastic shortening or extension at the time of application of prestress and/or external loads (ksi) (5.9.3.1)
Δf_{pF}	=	loss due to friction (ksi) (5.9.3.1)
Δf_{pLT}	=	losses due to long-term shrinkage and creep of concrete, and relaxation of the steel (ksi) (5.9.3.1)
Δf_{pR1}	=	prestress loss due to relaxation of prestressing strands between time of transfer and deck placement (ksi) (5.9.3.4.1)
Δf_{pR2}	=	prestress loss due to relaxation of prestressing strands in composite section between time of deck placement and final time (ksi) (5.9.3.4.1)
Δf_{pSD}	=	prestress loss due to shrinkage of girder concrete between time of deck placement and final time (ksi) (5.9.3.4.1)
Δf_{pSR}	=	prestress loss due to shrinkage of girder concrete between transfer and deck placement (ksi) (5.9.3.4.1)
Δf_{pSS}	=	prestress gain due to shrinkage of deck in composite section (ksi) (5.9.3.4.1)
Δf_{pT}	=	total loss (ksi) (5.9.3.1)
$\Delta \ell$	=	unit length segment of girder (in.) (C5.7.4.5)
δ	=	duct diameter correction factor, taken as 2.0 for grouted ducts (5.7.3.3)
δ_1	=	time-dependent multiplier corresponding to prestressing and girder self-weight (C5.12.3.3.2)
δ_2	=	time-dependent multiplier corresponding to deck weight (C5.12.3.3.2)
ϵ_{bdf}	=	shrinkage strain of girder between time of deck placement and final time (in./in.) (5.9.3.4.3a)
ϵ_{bid}	=	concrete shrinkage strain of girder between time of transfer and deck placement (in./in.) (5.9.3.4.2a)
ϵ_{cl}	=	compression-controlled strain limit in the extreme tension steel (in./in.) (5.5.4.2)
ϵ_{cu}	=	failure strain of concrete in compression (in./in.) (5.6.4.4)
ϵ_{ddf}	=	shrinkage strain of deck concrete between placement and final time (in./in.) (5.9.3.4.3d)
$\epsilon_{effective}$	=	effective concrete shrinkage strain (in./in.) (C5.12.3.3.3)
ϵ_s	=	net longitudinal tensile strain in the section at the centroid of the tension reinforcement (in./in.) (5.7.3.4.2)
ϵ_{sh}	=	concrete shrinkage strain at a given time (in./in.); unrestrained shrinkage strain for deck concrete (in./in.) (5.4.2.3.3) (C5.12.3.3.3)
ϵ_t	=	net tensile strain in extreme tension steel at nominal resistance (in./in.) (5.5.4.2)
ϵ_{tl}	=	tension-controlled strain limit in the extreme tension steel (in./in.) (5.5.4.2)
ϵ_x	=	longitudinal strain at the mid-depth of the member (in./in.) (B5.2)
θ	=	angle of inclination of diagonal compressive stresses (degrees) (5.7.3.3)
θ_s	=	angle between strut and longitudinal axis of the member (degrees) (5.8.2.2)
κ	=	correction factor for closely spaced anchorages; multiplier for strand development length (5.8.4.5.2) (5.9.4.3.2)
λ	=	concrete density modification factor (5.4.2.8)
λ_{cf}	=	coating factor (5.10.8.2.1a)

λ_{duct}	=	shear strength reduction factor accounting for the reduction in the shear resistance provided by transverse reinforcement due to the presence of a grouted post-tensioning duct, taken as 1.0 for ungrouted post-tensioning ducts and with a reduced web or flange width to account for the presence of ungrouted duct. (5.7.3.3)
λ_{er}	=	excess reinforcement factor (5.10.8.2.1a)
λ_{rc}	=	reinforcement confinement factor (5.10.8.2.1a)
λ_{rl}	=	reinforcement location factor (5.10.8.2.1a)
λ_w	=	wall slenderness ratio for hollow columns (5.6.4.7.1)
λ_{Δ}	=	multiplier used for calculating additional time-dependent deflection (5.6.3.5.2b)
μ	=	friction factor (5.7.4.3) (5.12.3.3.1)
ξ	=	time-dependent factor for sustained loads (5.6.3.5.2b)
ρ'	=	ratio of A'_s to bd (5.6.3.5.2b)
ρ_h	=	ratio of area of horizontal shear reinforcement to area of gross concrete area of a vertical section (5.11.4.2)
ρ_s	=	ratio of spiral or hoop reinforcement to total volume of column core (5.6.4.6)
ρ_v	=	ratio of area of vertical shear reinforcement to area of gross concrete area of a horizontal section (5.11.4.2)
τ	=	shear stress in web vertical shear (5.9.2.3.3)
ϕ	=	resistance factor (5.5.4.2)
ϕ_{cont}	=	girder web continuity factor (5.9.5.4.4d)
ϕ_{duct}	=	diameter of post-tensioning duct present in the girder web within depth d , (in.) (5.7.3.3)
ϕ_w	=	hollow column reduction factor (5.6.4.7.2c)
$\psi(t, t_i)$	=	creep coefficient for loading applied at t_i and sustained for a duration of time, t (5.4.2.3.2)
$\psi_b(t_d, t_i)$	=	girder creep coefficient at time of deck placement due to loading introduced at transfer (5.9.3.4.2b)
$\psi_b(t_f, t_d)$	=	girder creep coefficient at final time due to loading at deck placement; creep coefficient of girder concrete at final time due to loading introduced shortly after deck placement (overlays, barriers, etc.) (5.9.3.4.3b) (5.9.3.4.3d)
$\psi_b(t_f, t_i)$	=	girder creep coefficient at final time due to loading introduced at transfer (5.9.3.4.2a)
$\psi_d(t_f, t_d)$	=	creep coefficient of deck concrete at final time due to loading introduced shortly after deck placement (overlays, barriers, etc.) (5.9.3.4.3d)

5.4—MATERIAL PROPERTIES

5.4.1—General

Designs should be based on the material properties cited herein and on the use of materials that conform to the standards for the grades of construction materials as specified in *AASHTO LRFD Bridge Construction Specifications*.

When other grades or types of materials are used, their properties, including statistical variability, shall be established prior to design. The minimum acceptable properties and test procedures for such materials shall be specified in the contract documents.

In addition and secondary to the specifications provided herein, post-tensioning materials shall conform to the requirements of PTI/ASBI M50.3-19 and PTI M55.1-19.

The contract documents shall define the grades or properties of all materials to be used.

5.4.2—Normal Weight and Lightweight Concrete

5.4.2.1—Compressive Strength

For each component, the compressive strength of concrete for use in design, f'_c , or the class of concrete shall be shown in the contract documents.

The design concrete compressive strengths upon which the provisions of this Section are based are given in Article 5.1. Design concrete compressive strengths

C5.4.2.1

The evaluation of the strength of the concrete used in the work should be based on test cylinders produced, tested, and evaluated in accordance with Section 8 of the *AASHTO LRFD Bridge Construction Specifications*.

This Section was originally developed based on an upper limit of 10.0 ksi for the design concrete

above 10.0 ksi for normal weight concrete shall be used only when allowed by specific articles or when physical tests are made to establish the relationships between the concrete strength and other properties. Concrete with compressive strengths used in design below 2.4 ksi shall not be used in structural applications.

The design concrete compressive strength for prestressed concrete and decks shall not be less than 4.0 ksi.

In special cases where physical properties in addition to compressive strength are required for a structure to perform as intended, the additional properties shall be specified in the contract documents.

compressive strength of normal weight concrete. As research information for concrete compressive strengths greater than 10.0 ksi has become available, individual articles have been revised or extended to allow their use with higher strength concretes. Appendix C5 contains a listing of the articles affected by the design concrete compressive strengths and their current upper limit.

It is common practice that the compressive strength of concrete for use in design, or the Owner's specified strength if higher, be attained 28 days after placement. Other maturity ages may be assumed for design and specified for components that will receive loads at times appreciably different than 28 days after placement.

It is recommended that the classes of concrete shown in the *AASHTO LRFD Bridge Construction Specifications*, Section 8, be used wherever appropriate.

These classes are intended for use as follows:

- Class A concrete is generally used for all elements of structures, except when another class is more appropriate, and specifically for concrete exposed to saltwater.
- Class B concrete is used in footings, pedestals, massive pier shafts, and gravity walls.
- Class C concrete is used in thin sections, such as reinforced railings less than 4.0 in. thick, for filler in steel grid floors, etc.
- Class P concrete is used when strengths in excess of 4.0 ksi are required. For prestressed concrete, consideration should be given to limiting the nominal aggregate size to 0.75 in.
- Class S concrete is used for concrete deposited underwater in cofferdams to seal out water.

Strengths above 5.0 ksi should be used only when the availability of materials for such concrete in the locale is verified.

In the evaluation of existing structures, it may be appropriate to modify f'_c and the other attendant structural properties specified for the original construction to recognize the strength gain or any strength loss due to age or deterioration after 28 days. Such modified f'_c values should be determined by core samples of sufficient number and size to represent the concrete in the work, tested in accordance with AASHTO T 24M/T 24 (ASTM C42/C42M).

For concrete Classes A, A(AE), and P used in or over saltwater, the water/cement ratio (W/CM) shall be specified not to exceed 0.45.

The sum of portland cement and other cementitious materials shall be specified not to exceed 800 lb/yd³, except for Class P (HPC) concrete where the sum of portland cement and other cementitious materials shall be specified not to exceed 1,000 lb/yd³.

5.4.2.2—Coefficient of Thermal Expansion

The coefficient of thermal expansion should be determined by the laboratory tests on the specific mix to be used.

In the absence of more precise data, the thermal coefficient of expansion may be taken as:

- For normal weight concrete: $6.0 \times 10^{-6}/^{\circ}\text{F}$, and
- For lightweight concrete: $5.0 \times 10^{-6}/^{\circ}\text{F}$

5.4.2.3—Creep and Shrinkage**5.4.2.3.1—General**

Values of creep and shrinkage, specified herein and in Articles 5.9.3.3 and 5.9.3.4, shall be used to determine the effects of creep and shrinkage on the loss of prestressing force in bridges other than segmentally constructed ones. These values in conjunction with the moment of inertia, as specified in Article 5.6.3.5.2, may be used to determine the effects of shrinkage and creep on deflections.

These provisions are applicable for design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi. In the absence of more accurate data, the shrinkage coefficients may be assumed to be 0.0002 after 28 days and 0.0005 after one year of drying.

Except for segmentally constructed bridges, or where mix-specific data are not available, estimates of shrinkage and creep may be made using the provisions of any of the following:

- Articles 5.4.2.3.2 and 5.4.2.3.3,
- The *fib Model Code for Concrete Structures 2010* (fib, 2010),
- CEB-FIP Model Code 1990 (CEB, 1990), or
- ACI 209.2R-08.

For segmentally constructed bridges, estimates of shrinkage and creep may be made using the provisions of the *fib Model Code for Concrete Structures 2010* (fib, 2010), or the CEB-FIP Model Code 1990 (CEB, 1990). In addition, a more precise estimate shall be made, including the effect of all of the following:

- specific materials, when known,
- structural dimensions,
- site conditions,
- construction methods, and
- concrete age at various stages of erection.

C5.4.2.2

The thermal coefficient depends primarily on the types and proportions of aggregates used and on the degree of saturation of the concrete.

The thermal coefficient of normal weight concrete can vary between 3.0 to $8.0 \times 10^{-6}/^{\circ}\text{F}$, with limestone and marble aggregates producing the lower values, and chert and quartzite the higher. Only limited determinations of these coefficients have been made for lightweight concretes. They are in the range of 4.0 to $6.0 \times 10^{-6}/^{\circ}\text{F}$ and depend on the amount of natural sand and type of lightweight aggregate used.

Additional information may be found in ACI 343 (1995), ACI 209 (2008), and ACI 213 (2014).

C5.4.2.3.1

Creep and shrinkage of concrete are variable properties that depend on a number of factors, some of which may not be known at the time of design.

Without specific physical tests or prior experience with the materials, the use of the empirical methods referenced in these specifications cannot be expected to yield results with errors less than ± 50 percent.

Values of modulus of elasticity, creep factors, and shrinkage factors should be taken from a consistent source.

Comparisons of creep coefficients show that Article 5.4.2.3.2 and ACI 209 estimate lower creep coefficients than the *fib Model Code for Concrete Structures 2010* (fib, 2010) and the CEB-FIP Model Code 1990 (CEB, 1990) in segmentally constructed bridges. The use of the *fib Model Code for Concrete Structures 2010* (fib, 2010) is recommended by the American Segmental Bridge Institute for creep and shrinkage calculations of segmentally constructed bridges.

Where mix-specific data are available, more precise models can be utilized for creep and shrinkage estimates for segmental bridges, including the B4 model from Wendner et al. (2013).

5.4.2.3.2—Creep

The creep coefficient may be taken as:

$$\psi(t, t_i) = 1.9k_s k_{hc} k_f k_{td} t_i^{-0.118} \quad (5.4.2.3.2-1)$$

in which:

$$k_s = 1.45 - 0.13(V/S) \geq 1.0 \quad (5.4.2.3.2-2)$$

$$k_{hc} = 1.56 - 0.008H \quad (5.4.2.3.2-3)$$

$$k_f = \frac{5}{1 + f'_{ci}} \quad (5.4.2.3.2-4)$$

$$k_{td} = \frac{t}{12 \left(\frac{100 - 4f'_{ci}}{f'_{ci} + 20} \right) + t} \quad (5.4.2.3.2-5)$$

where:

H = average annual ambient relative humidity (percent). In the absence of better information, H may be taken from Figure 5.4.2.3.3-1.

k_s = factor for the effect of the volume-to-surface ratio of the component

k_f = factor for the effect of concrete strength

k_{hc} = humidity factor for creep

k_{td} = time development factor

t = maturity of concrete (day)

t_i = age of concrete at time of load application (day)

V/S = volume-to-surface ratio (in.)

f'_{ci} = design concrete compressive strength at time of prestressing for pretensioned members and at time of initial loading for nonprestressed members. If concrete age at time of initial loading is unknown at design time, f'_{ci} may be taken as $0.80 f'_c$ (ksi).

The surface area used in determining the volume-to-surface ratio should include only the area that is exposed to atmospheric drying. For poorly ventilated enclosed cells, only 50 percent of the interior perimeter should be used in calculating the surface area. For precast members with cast-in-place topping, the total precast surface should be used. For pretensioned stemmed members (I-beams, T-beams, and box beams), with an

C5.4.2.3.2

The methods of determining creep and shrinkage, as specified herein and in Article 5.4.2.3.3, are based on Huo et al. (2001), Al-Omaishi (2001), Tadros et al. (2003), Rizkalla et al. (2007), and Collins and Mitchell (1991). These methods are based on the recommendation of ACI Committee 209 as modified by additional published data. Other applicable references include Rusch et al. (1983), Bazant and Wittman (1982), and Ghali and Favre (1986).

The creep coefficient is applied to the compressive strain caused by permanent loads in order to obtain the strain due to creep.

Creep is influenced by the same factors as shrinkage, and also by the following:

- magnitude and duration of the stress,
- maturity of the concrete at the time of loading, and
- temperature of concrete.

Creep shortening of concrete under permanent loads is generally in the range of 0.5 to 4.0 times the initial elastic shortening, depending primarily on concrete maturity at the time of loading.

The time development of shrinkage, given by Eq. 5.4.2.3.2-5, is proposed to be used for both precast concrete and cast-in-place concrete components of a bridge member, and for both accelerated curing and moist curing conditions. This simplification is based on a parametric study documented in Tadros et al. (2003), on prestress losses in high-strength concrete. It was found that various time development prediction methods have virtually no impact on the final creep and shrinkage coefficients, prestress losses, or member deflections. It was also observed in that study that use of modern concrete mixtures with relatively low water/cement ratios and with high-range water reducing admixtures, has caused time development of both creep and shrinkage to have similar patterns. They have a relatively rapid initial development in the first several weeks after concrete placement and a slow further growth thereafter. For calculation of intermediate values of prestress losses and deflections in cast-in-place segmental bridges constructed with the balanced cantilever method, it may be warranted to use actual test results for creep and shrinkage time development using local conditions. Final losses and deflections would be substantially unaffected whether Eq. 5.4.2.3.2-5 or another time-development formula is used.

The factors for the effects of volume-to-surface ratio are an approximation of the following formulas:

average web thickness of 6.0 to 8.0 in., the value of k_s may be taken as 1.00.

For creep:

$$k_c = \left[\frac{\frac{t}{26e^{0.36(V/S)} + t}}{\frac{t}{45 + t}} \right] \left[\frac{1.80 + 1.77e^{-0.54(V/S)}}{2.587} \right] \quad (C5.4.2.3.2-1)$$

For shrinkage:

$$k_s = \left[\frac{\frac{t}{26e^{0.36(V/S)} + t}}{\frac{t}{45 + t}} \right] \left[\frac{1064 - 94(V/S)}{923} \right] \quad (C5.4.2.3.2-2)$$

The maximum V/S ratio considered in the development of Eqs. C5.4.2.3.2-1 and C5.4.2.3.2-2 was 6.0 in.

Ultimate creep and shrinkage are less sensitive to surface exposure than intermediate values at an early age of concrete. For accurately estimating intermediate deformations of such specialized structures as segmentally constructed balanced cantilever box girders, it may be necessary to resort to experimental data or use the more detailed Eqs. C5.4.2.3.2-1 and C5.4.2.3.2-2.

5.4.2.3.3—Shrinkage

For concretes devoid of shrinkage-prone aggregates, the strain due to shrinkage, ϵ_{sh} , at time, t , may be taken as:

$$\epsilon_{sh} = k_s k_{hs} k_f k_{td} 0.48 \times 10^{-3} \quad (5.4.2.3.3-1)$$

in which:

$$k_{hs} = (2.00 - 0.014 H) \quad (5.4.2.3.3-2)$$

where:

k_{hs} = humidity factor for shrinkage

If the concrete is exposed to drying before 5 days of curing have elapsed, the shrinkage as determined in Eq. 5.4.2.3.3-1 should be increased by 20 percent.

C5.4.2.3.3

Large concrete members may undergo substantially less shrinkage than that measured by laboratory testing of small specimens of the same concrete. The constraining effects of reinforcement and composite actions with other elements of the bridge tend to reduce the dimensional changes in some components.

Figure 5.4.2.3.3-1—Average Annual Ambient Relative Humidity, in Percent

5.4.2.4—Modulus of Elasticity

In the absence of measured data, the modulus of elasticity, E_c , for design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi, with unit weights between 0.090 and 0.155 kcf, may be taken as:

$$E_c = 120,000 K_1 w_c^{2.0} f_c'^{0.33} \quad (5.4.2.4-1)$$

where:

- E_c = modulus of elasticity of concrete (ksi)
- K_1 = correction factor for source of aggregate to be taken as 1.0 unless determined by physical test, and as approved by the Owner
- w_c = unit weight of concrete (kcf); refer to Table 3.5.1-1 or Article C5.4.2.4
- f'_c = compressive strength of concrete for use in design (ksi)

C5.4.2.4

See commentary on strength in Article 5.4.2.1.

For normal weight concrete with $w_c = 0.145$ kcf, E_c may be taken as:

$$E_c = 2,500 f_c'^{0.33} \quad (C5.4.2.4-1)$$

Eqs. 5.4.2.4-1 and C5.4.2.4-1 are based upon the research of Greene and Graybeal (2013).

For normal weight concrete with $w_c = 0.145$ kcf and design compressive strengths up to 10.0 ksi, E_c may be determined from either of the following:

$$E_c = 33,000 K_1 w_c^{1.5} \sqrt{f'_c} \quad (C5.4.2.4-2)$$

$$E_c = 1,820 \sqrt{f'_c} \quad (C5.4.2.4-3)$$

Eqs. C5.4.2.4-2 and C5.4.2.4-3 are equations from previous editions of these Specifications, which are not as accurate for lightweight concrete and higher compressive strengths.

Test data show that the modulus of elasticity of concrete is influenced by the stiffness of the aggregate. The factor K_1 is included to allow the calculated modulus to be adjusted for different types of aggregate and local materials. Unless a value has been determined by physical tests, K_1 should be taken as 1.0. Use of a measured K_1 factor permits a more accurate prediction of modulus of elasticity and other values that utilize it.

5.4.2.5—Poisson's Ratio

Unless determined by physical tests, Poisson's ratio may be assumed as 0.2 for design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi. For components expected to be subject to cracking, the effect of Poisson's ratio may be neglected.

5.4.2.6—Modulus of Rupture

Unless determined by physical tests, the modulus of rupture, f_r , for design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi may be taken as $0.24 \lambda \sqrt{f'_c}$ where λ is the concrete density modification factor as specified in Article 5.4.2.8.

Where physical tests are used to determine modulus of rupture, the tests shall be performed in accordance with AASHTO T 97 and shall be performed on concrete using the same proportions and materials as specified for the structure.

5.4.2.7—Tensile Strength

In general, the tensile strength of concrete may be taken as the splitting tensile strength determined in accordance with AASHTO T 198 (ASTM C496/C496M).

C5.4.2.5

This is a ratio between the lateral and axial strains of an axially and/or flexurally loaded structural element.

C5.4.2.6

Most modulus of rupture test data on normal weight concrete is between $0.24\sqrt{f'_c}$ and $0.37\sqrt{f'_c}$ (ksi) (Walker and Bloem, 1960; Khan, Cook, and Mitchell, 1996). A value of $0.37\sqrt{f'_c}$ has been recommended for the prediction of the tensile strength of high-strength concrete (ACI 363, 2010). However, the modulus of rupture is sensitive to curing methods and nearly all of the test units in the dataset mentioned previously were moist cured until testing. Carrasquillo et al. (1981) note a 26 percent reduction in the 28-day modulus of rupture if high-strength units were allowed to dry after seven days of moist curing over units that were moist cured until testing.

The flexural cracking stress of concrete members has been shown to significantly reduce with increasing member depth. Shioya et al. (1989) observed that the flexural cracking strength is proportional to $H^{-0.25}$ where H is the overall depth of the flexural member in inches. Based on this observation, a 36.0 in. deep girder should achieve a flexural cracking stress that is 36 percent lower than that of a 6.0 in. deep modulus of rupture test.

Since modulus of rupture units were either 4.0 or 6.0 in. deep and moist cured up to the time of testing, the modulus of rupture should be significantly greater than that of an average size bridge member composed of the same concrete. Therefore, $0.24\sqrt{f'_c}$ is appropriate for checking minimum reinforcement in Article 5.6.3.3.

The properties of higher-strength concretes are particularly sensitive to the constitutive materials. If test results are to be used in design, it is imperative that tests be made using concrete with not only the same mix proportions but also the same materials as the concrete used in the structure.

The given values may be unconservative for tensile cracking caused by restrained shrinkage, anchor zone splitting, and other such tensile forces caused by effects other than flexure. The direct tensile strength stress should be used for these cases.

C5.4.2.7

The tensile strength may be estimated as the splitting tensile strength, f_{ct} , which can be computed from Eq. 5.4.2.8-1 as $f_{ct} = 0.213\lambda\sqrt{f'_c}$, using λ from Eq. 5.4.2.8-2.

5.4.2.8—Concrete Density Modification Factor

The concrete density modification factor, λ , shall be determined as:

- Where the splitting tensile strength, f_{ct} , is specified:

$$\lambda = 4.7 \frac{f_{ct}}{\sqrt{f'_c}} \leq 1.0 \quad (5.4.2.8-1)$$

- Where f_{ct} is not specified:

$$0.75 \leq \lambda = 7.5 w_c \leq 1.0 \quad (5.4.2.8-2)$$

- Where normal weight concrete is used, λ shall be taken as 1.0.

C5.4.2.8

The concrete density modification factor was developed based on available test data. There is a lack of data for concrete mix designs wherein a large majority of the fine aggregate is lightweight and a large majority of the coarse aggregate is normal weight. The concrete density modification factor, λ , is based on work on mechanical properties, development of reinforcement, and shear by Greene and Graybeal (2013, 2014, 2015), respectively.

The determination of λ as defined in Eq. 5.4.2.8-2 is illustrated in Figure C5.4.2.8-1.

Figure C5.4.2.8-1—Illustration of λ as a Function of Unit Weight in Eq. 5.4.2.8-2

5.4.3—Reinforcing Steel

5.4.3.1—General

Reinforcing bars, deformed wire, cold-drawn wire, and deformed or plain welded wire reinforcement shall conform to the material standards as specified in Article 9.2 of the *AASHTO LRFD Bridge Construction Specifications*.

Reinforcement shall be deformed, except that plain bars or plain wire may be used for spirals, hoops, and wire fabric.

The nominal yield strength shall be the minimum as specified for the grade of steel. Yield strengths in excess of 75.0 ksi up to 100 ksi may be used for design permitted by Article 5.4.3.3. The yield strength or grade of the bars or wires shall be shown in the contract documents. Bars with yield strengths less than 60.0 ksi shall be used only with the approval of the Owner.

C5.4.3.1

Unlike reinforcing bars with yield strengths below 75.0 ksi, reinforcing bars with yield strengths exceeding 75.0 ksi usually do not have well-defined yield plateaus. Consequently, different methods are used in different standards to establish yield strengths. These include the 0.2 percent offset and the 0.35 percent or 0.50 percent extension methods. For design purposes, the value of f_y should be the same as the specified minimum yield strength defined in the material standard. Based on research by Shahrooz et al. (2011), certain articles now allow the use of reinforcement with yield strengths up to 100 ksi for all elements and connections in Seismic Zone 1.

Where ductility is to be assured or where welding is required, steel conforming to the requirements of ASTM A706/A706M shall be specified. Reinforcement to be welded and the weld design and details shall be specified in the contract documents. Welding of steel reinforcement shall conform to the current edition of the AWS D1.4, *Structural Welding Code-Steel Reinforcement Bars*.

5.4.3.2—Modulus of Elasticity

The modulus of elasticity, E_s , of steel reinforcement shall be assumed as 29,000 ksi for specified minimum yield strengths up to 100 ksi.

5.4.3.3—Special Applications

Where permitted by specific Articles listed in Appendix D5, reinforcement with specified minimum yield strengths of less than or equal to 100 ksi may be used for all elements and connections in Seismic Zone 1.

The following ASTM designations and grades of reinforcing steel shall be used in members containing potential plastic hinge regions:

- For bridges in Seismic Zones 2 and 3, ASTM A706/A706M Grade 60, except that ASTM A615/A615M Grade 60 or ASTM A706/A706M Grade 80 may be used with the Owner's approval.
- For bridges in Seismic Zone 4, ASTM A706/A706M Grade 60, except that ASTM A706/A706M Grade 80 may be used with the Owner's approval.

In Seismic Zones 2, 3, and 4, unless prohibited by the owner, the following ASTM designations and grades of reinforcing steel may be used in members not containing potential plastic hinge regions:

- ASTM A615/A615M Grades 60, 80, and 100
- ASTM A706/A706M Grades 60 and 80
- ASTM A1035/A1035M Grade 100

5.4.4—Prestressing Steel

5.4.4.1—General

Uncoated, low-relaxation, seven-wire strand, or uncoated plain or deformed, high-strength bars, shall conform to either of the following materials standards, as specified for use in *AASHTO LRFD Bridge Construction Specifications*:

- AASHTO M 203/M 203M (ASTM A416/A416M), or

ASTM A706/A706M reinforcement should be considered for seismic design because of its well defined yield plateau.

C5.4.3.3

In 2004, ASTM published A1035/A1035M. This reinforcement has a yield strength equal to or greater than 100 ksi and offers the potential for corrosion resistance.

Material and column specimen tests conducted by Overby et al. (2015), Barbosa et al. (2016), and Barclay and Kowalsky (2020) showed that ASTM A706/A706M Grade 80 reinforcing steel has acceptable elongation characteristics and may be used in members containing plastic hinge regions to reduce steel reinforcement congestion.

When Grade 60 reinforcing steel along with the minimum specified material properties are used for designing members subjected to high load demands, a large amount of reinforcing steel may be needed, which may cause rebar congestion and construction challenges. The use of high strength bar reinforcement may result in a more reasonable amount of reinforcing steel in the members, leading to savings in material, shipping, and placement costs. Reducing reinforcement congestion also leads to better quality of concrete construction.

- AASHTO M 275/M 275M (ASTM A722/A722M).

Requirements for these steels may be taken as specified in Table 5.4.4.1-1.

Table 5.4.4.1-1—Properties of Prestressing Strand and Bar

Material	Grade or Type	Diameter (in.)	Tensile Strength, f_{pu} (ksi)	Yield Strength, f_{py} (ksi)
Strand	270 ksi	0.375 to 0.6	270	90% of f_{pu}
Bar	Type 1, Plain	0.75 to 1.375	150	85% of f_{pu}
	Type 2, Deformed	0.625 to 2.5	150	80% of f_{pu}

Where complete prestressing details are included in the contract documents, the size and grade or type of steel shall be shown. If the plans indicate only the prestressing forces and locations of application, the choice of size and type of steel shall be left to the Contractor, subject to the Engineer's approval.

5.4.4.2—Modulus of Elasticity

If more precise data are not available, the modulus of elasticity for prestressing steel, based on nominal cross-sectional area, may be taken as:

for strand: $E_p = 28,500$ ksi, and
for bar: $E_p = 30,000$ ksi

5.4.5—Post-Tensioning Anchorages and Couplers

Anchorages and tendon couplers shall conform to the requirements of Article 10.3.2 of *AASHTO LRFD Bridge Construction Specifications* and PTI/ASBI M50.3-19.

The required tendon Protection Level (PL) shall be specified in the contract documents.

C5.4.5

Section 3.0 Post-Tensioning System (PTS) Tendon Protection Levels, and adjacent commentary, of PTI/ASBI M50.3-19 provide information on selection of a PL and the associated performance requirements for each PL. This includes reference to Fédération International du Béton (*fib*) Bulletin 33, Recommendation, “Durability of post-tensioning tendons” and Krauser, *fib* symposium Prague (2011), “Selecting Post-Tensioning Tendon Protection Levels.”

Protection Level 2 (PL2) is considered the default PL.

5.4.6—Post-Tensioning Ducts

5.4.6.1—General

Ducts for tendons may be metallic or nonmetallic as identified in the PL requirements of Section 3.0 of PTI/ASBI M50.3-19 and shall conform to the requirements of Article 10.8 of the *AASHTO LRFD Bridge Construction Specifications*.

The minimum radius of curvature of tendon ducts shall take into account the tendon size, duct type and shape, and the location relative to the stressing

C5.4.6.1

The use of nonmetallic duct is generally recommended in corrosive environments.

The contract documents should indicate the specific type of duct material to be used when only one type is to be allowed.

anchorage; subject to the manufacturer's recommendations.

Where polymer ducts are used and the tendons are to be bonded, the bonding characteristics of polymer ducts to the concrete and the grout should be investigated in accordance with Section 4.4.4 of PTI/ASBI M50.3-19.

The effects of grouting pressure on the ducts and the surrounding concrete shall be investigated. Ducts shall conform to the requirements of Section 4.4 of PTI/ASBI M50.3-19.

The maximum support interval for the ducts during construction shall be indicated in the contract documents and shall conform to Article 10.4.1.1 of the *AASHTO LRFD Bridge Construction Specifications*.

5.4.6.2—Size of Ducts

The inside diameter of ducts shall be at least 0.25 in. larger than the nominal diameter of single strand tendons. The inside diameter of ducts shall be at least 0.5 in. larger than the nominal diameter of single bar tendons. For prestressing bars with couplers, the inside diameter of ducts shall be at least 0.5 in. larger than the outside diameter of the bar and/or coupler. For multiple strand tendons, the inside cross-sectional area of the duct shall be at least 2.5 times the net area of the prestressing steel.

The size of ducts in structural concrete shall not exceed 0.54 times the least gross concrete thickness at the duct.

5.4.6.3—External Tendons Passing through Deviation Saddles

External tendons passing through deviation saddles shall utilize either of the following details:

- Galvanized rigid steel pipe ducts
- Diabolos

The minimum tendon radius at deviation saddles shall be as large as permitted by the geometry of the tendon and deviation saddle but, unless verified by testing, shall not be less than:

$$R_{min,d} = 0.306\sqrt{f_{pu}A_{ps}} \geq 6.6 \text{ ft} \quad (5.4.6.3-1)$$

where:

- $R_{min,d}$ = minimum tendon radius at deviation saddle (ft)
 f_{pu} = specified tensile strength of prestressing steel (ksi)
 A_{ps} = area of prestressing steel (in.²)

C5.4.6.2

Information on duct cross sectional areas is provided in Section 4.3.5 of PTI/ASBI M50.3-19.

Research by Moore et. al. (2015) examined shear resistance of members with ducts and proposed a λ_{duct} factor to modify V_s for the presence of ducts. The testing and analysis in this research examined cases up to a ratio of 54 percent, a likely pragmatic maximum given cover, shear reinforcing, and duct size. The research was also limited to duct stacks and does not apply to bundled ducts. See Article 5.7.3.3.

C5.4.6.3

The minimum tendon radius specified by Article 5.4.6.3 is similar to the minimum radii recommended for external tendons in Ledesma, 2019:

Tendon Size	Minimum Radius at Deviators (feet)
7-0.6"	6.6
12-0.6"	8.2
15-0.6"	9.0
19-0.6"	9.8
22-0.6"	10.7
27-0.6"	11.5
31-0.6"	12.3

The above publication also recommends the following minimum radii and tangent lengths at anchorages:

To utilize a smaller radius than specified by this Article, the testing specified by Article 10.3.2.2 of the *AASHTO LRFD Bridge Construction Specifications* for rigid pipe duct and plastic ducts through diabolos and Article 10.8.3 of the *AASHTO LRFD Bridge Construction Specifications* for plastic ducts through diabolos shall be performed to verify the adequacy of the proposed details.

The galvanized rigid steel pipe ducts in the deviation saddles shall meet the requirements set forth in Article 10.8.2, and the external plastic tendon ducts passing through the deviation saddles shall meet the requirements set forth in Article 10.8.3, of the *AASHTO LRFD Bridge Construction Specifications*.

Tendon Size	Minimum Radius at Anchorages (feet)	Minimum Tangent Length at Anchorages (feet)
7-0.6"	9.8	2.5
12-0.6"	11.5	3.3
15-0.6"	12.3	3.3
19-0.6"	13.1	3.9
22-0.6"	13.9	3.9
27-0.6"	14.8	4.3
31-0.6"	15.6	4.8

5.5—LIMIT STATES AND DESIGN METHODOLOGIES

5.5.1—General

5.5.1.1—Limit-State Applicability

Structural components shall be proportioned to satisfy the requirements at all appropriate service, fatigue, strength, and extreme event limit states at all stages during the life of the structure. Unless specified otherwise by the Owner, the load combinations and load factors specified in Section 3 and elsewhere in this Section shall be used.

Prestressed concrete structural components shall be proportioned for stresses and deformations for each stage that may be critical during construction, stressing, handling, transportation, and erection as well as during the service life of the structure of which they are part.

Stress concentrations due to prestressing or other loads and to restraints or imposed deformations shall be considered.

The effects of imposed deformations due to shrinkage, temperature change, creep, prestressing, and movements of supports shall be investigated.

For determinate structures, experience may show that evaluating the redistribution of force effects as a result of creep and shrinkage is unnecessary.

5.5.1.2—Design Methodologies

5.5.1.2.1—General

Conventional beam theory based on Bernoulli's plane section hypothesis shall be considered applicable for the service and fatigue limit states. At the strength and extreme event limit states, regions of a concrete structure shall be characterized by their behavior as B-Regions (beam or Bernoulli) or D-Regions (disturbed or discontinuity). Bernoulli's hypothesis of straight-line strain profile, and therefore conventional beam theory, may be assumed to apply in B-Regions. A more complex variation in stress and strain exists in D-Regions as shown in Figure 5.5.1.2.1-1, where the effective depth of the member, d , is defined as the

C5.5.1.2.1

D-Regions occur in the vicinity of load or geometric discontinuities. In Figure 5.5.1.2.1-1, the applied load and support reactions are discontinuities that "disturb" the regions of the member near the locations at which they act. Frame corners, dapped ends, openings, and corbels are examples of geometric discontinuities which correspond to the existence of D-Regions.

The distribution of strains through the member depth in D-Regions is nonlinear, and the assumptions that underlie the sectional design procedure are therefore invalid. According to St. Venant's principle, an elastic stress analysis indicates that a linear distribution of

distance between the extreme compression fiber and the centroid of the primary longitudinal reinforcement.

Figure 5.5.1.2.1-1—Stress Trajectories within B- and D-Regions of a Flexural Member (adapted from Birrcher et al., 2009)

D-Regions shall be taken to encompass locations with abrupt changes in geometry or concentrated forces. Based upon St. Venant's principle, D-Regions may be assumed to span one member depth on either side of the discontinuity in geometry or force.

Where the effective depth changes along the component the length of the D-Regions should be varied accordingly.

5.5.1.2.2—B-Regions

Design practices for B-Regions shall be based on a sectional model for behavior. Design for flexure in B-Regions shall be based on the conventional beam theory of Article 5.6 while the design for shear in B-Regions shall be based on conventional beam theory in conjunction with the truss analogy of Article 5.7.

Conventional beam theory is applicable to all limit states.

5.5.1.2.3—D-Regions

For the strength and extreme event limit states, the strut-and-tie method (STM) of Article 5.8.2 or other methods from Article 5.8.3 or Article 5.8.4 may be applied for the design of all types of D-Regions in structural concrete.

The most familiar types of D-Regions, such as beam ends, diaphragms, deep beams, brackets, corbels, and beam ledges, may be designed by the empirical approaches or the legacy detailing practices such as those found in Article 5.8.4.

stress can be assumed at approximately one member depth from a load or geometric discontinuity. In other words, a nonlinear stress distribution exists within one member depth from the location where the discontinuity is introduced (Schlaich et al., 1987). D-Regions are therefore assumed to extend approximately a distance d from the applied load and support reactions in Figure 5.5.1.2.1-1. In the case of the reaction at an interior support, the disturbed region extends a distance d on each side of the reaction.

B-Regions occur between D-Regions, as shown in Figure 5.5.1.2.1-1. Plane sections are assumed to remain plane within B-Regions according to the primary tenets of beam theory, implying that a linear distribution of strains occurs through the member depth. The beam is therefore dominated by sectional behavior, and design can proceed on a section-by-section basis (i.e., sectional design). For the flexural design of a B-Region, the compressive stresses (represented by solid lines in Figure 5.5.1.2.1-1) are conventionally assumed to act over a rectangular stress block, while the tensile stresses (represented by dashed lines) are assumed to be carried by the longitudinal steel reinforcement.

C5.5.1.2.2

Sectional models are appropriate for the design of typical bridge girders, slabs, and other regions of components where the assumptions of traditional engineering beam theory are valid. This theory assumes that the response at a particular section depends only on the calculated values of the sectional force effects, i.e., moment, shear, axial load, and torsion, and does not consider the specific details of how the force effects were introduced into the member.

C5.5.1.2.3

These specifications recognize three general classes of analysis methods for the design of D-Regions:

- The STM introduced here and explained in more detail in Article 5.8.2.
- Elastic analysis introduced in Article 5.8.3.
- Legacy practices which are empirical and other approximate methods usually developed before refined analysis methods such as the STM became more widely used and are described in Article 5.8.4. Use of these methods is not preferred and is expected to decline in time.

Plasticity-based methods, which include the STM, can be classified into two categories: upper-bound and lower-bound methods. The upper-bound solutions approach the resistance from the unconservative side, while lower-bound solutions approach the resistance from the conservative side. The STM is a lower-bound design method. As such, it adheres to these principles:

(1) the truss model is in equilibrium with external forces, and (2) the concrete element has enough deformation capacity to accommodate the assumed distribution of forces (Schlaich et al., 1987). Proper anchorage of the reinforcement is required. Additionally, the compressive forces in the concrete must not exceed the factored strut capacities, and the tensile forces within the strut-and-tie model must not exceed the factored tie capacities.

The STM recognizes the significance of how the loads are introduced into a disturbed region and how that region is supported, and is based on the assumption of straight line trajectories of internal stresses due to significant cracking beyond service loads. This method is also applicable to both B- and D-Regions, but it is typically not practical to apply the method to B-Regions.

5.5.2—Service Limit State

Actions to be considered at the service limit state shall be cracking, deformations, and concrete stresses, as specified in Articles 5.6.7, 5.6.3.5, and 5.9.2.3, respectively.

The cracking stress shall be taken as the modulus of rupture specified in Article 5.4.2.6.

5.5.3—Fatigue Limit State

5.5.3.1—General

Fatigue need not be investigated for concrete deck slabs in multigirder applications or reinforced-concrete box culverts.

In regions of compressive stress due to unfactored permanent loads and prestress in reinforced concrete components, fatigue shall be considered only if this compressive stress is less than the maximum tensile live load stress resulting from the Fatigue I load combination as specified in Table 3.4.1-1 in combination with the provisions of Article 3.6.1.4.

Fatigue of the reinforcement need not be checked for prestressed components designed to have extreme fiber tensile stress due to Service III limit state within the tensile stress limit specified in Table 5.9.2.3.2b-1. Structural components with a combination of prestressing strands and reinforcing bars that allow the tensile stress in the concrete to exceed the Service III limit specified in Table 5.9.2.3.2b-1 shall be checked for fatigue.

C5.5.3.1

Stresses measured in concrete deck slabs of bridges in service are far below infinite fatigue life, most probably due to internal arching action; see Article C9.7.2.

Fatigue evaluation for reinforced-concrete box culverts showed that the live load stresses in the reinforcement due to Fatigue I load combination did not reduce the member resistance at the strength limit state.

In determining the need to investigate fatigue, Table 3.4.1-1 specifies a load factor of 1.75 on the live load force effect resulting from the fatigue truck for the Fatigue I load combination. This factored live load force effect represents the greatest fatigue stress that the bridge will experience during its life.

Fatigue limit state load factor, girder distribution factors, and dynamic allowance cause fatigue limit state stress to be considerably less than the corresponding value determined from Service Limit State III. For prestressed components, the net concrete stress is usually significantly less than the concrete tensile stress limit specified in Table 5.9.2.3.2b-1. Therefore, the calculated flexural stresses are significantly reduced. For this situation, the calculated steel stress range, which is equal to the modular ratio times the concrete stress range, is almost always less than the steel fatigue stress range limit specified in Article 5.5.3.3.

For fatigue considerations, concrete members shall satisfy:

$$\gamma(\Delta f) \leq (\Delta F)_{TH} \quad (5.5.3.1-1)$$

where:

- γ = load factor specified in Table 3.4.1-1 for the Fatigue I load combination
- Δf = force effect, live load stress range due to the passage of the fatigue load as specified in Article 3.6.1.4 (ksi)
- $(\Delta F)_{TH}$ = constant-amplitude fatigue threshold, as specified in Article 5.5.3.2, 5.5.3.3, or 5.5.3.4, as appropriate (ksi)

For prestressed components in other than segmentally constructed bridges, the compressive stress due to the Fatigue I load combination and one-half the sum of the unfactored effective prestress and permanent loads shall not exceed $0.40f'_c$.

The section properties for fatigue investigations shall be based on cracked sections where the sum of stresses, due to unfactored permanent loads and prestress, and the Fatigue I load combination is tensile and exceeds $0.095\lambda\sqrt{f'_c}$, where λ is the concrete density modification factor as specified in Article 5.4.2.8.

5.5.3.2—Reinforcing Bars and Welded Wire Reinforcement

The constant-amplitude fatigue threshold, $(\Delta F)_{TH}$, for straight reinforcement and welded wire reinforcement without a cross weld in the high-stress region shall be taken as:

$$(\Delta F)_{TH} = 26 - \frac{22f_{min}}{f_y} \quad (5.5.3.2-1)$$

The constant-amplitude fatigue threshold, $(\Delta F)_{TH}$, for straight welded wire reinforcement with a cross weld in the high-stress region shall be taken as:

$$(\Delta F)_{TH} = 18 - 0.36f_{min} \quad (5.5.3.2-2)$$

where:

- f_{min} = minimum live-load stress resulting from the Fatigue I load combination, combined with the more severe stress from either the unfactored permanent loads or the unfactored permanent loads, shrinkage, and creep-induced external loads; positive if tension, negative if compression (ksi)
- f_y = specified minimum yield strength of reinforcement, not to be taken less than 60.0 ksi nor greater than 100 ksi

C5.5.3.2

With the permitted use of steel reinforcement having yield stresses above 75.0 ksi, the value of f_{min} is expected to increase. In previous versions of Eq. 5.5.3.2-1, an increase in f_{min} would result in a decrease in $(\Delta F)_{TH}$, regardless of the yield strength of the bar. Current data indicates that steel with a higher yield strength actually has a higher fatigue limit (DeJong and MacDougall, 2006). Eq. 5.5.3.2-1 has been calibrated such that there is no change to the value of $(\Delta F)_{TH}$ from earlier versions of this equation for cases of $f_y = 60.0$ ksi, but it now provides more reasonable values of $(\Delta F)_{TH}$ for higher-strength reinforcing bars. The values of 60.0 and 100 ksi are limits of substitution into Eq. 5.5.3.2-1, not a prohibition on providing reinforcement with other yield strengths.

Structural welded wire reinforcement has been increasingly used in bridge applications in recent years, especially as auxiliary reinforcement in bridge I- and box beams and as primary reinforcement in slabs. Design for shear has traditionally not included a fatigue check of the reinforcement as the member is expected to be uncracked under service conditions and the stress range in steel minimal. The stress range for steel bars has existed in previous editions. It is based on Helgason et al. (1976). The simplified form in this edition replaces the (r/h) parameter with the default value 0.3 recommended by Helgason et al. (1976). Inclusion of limits for welded wire reinforcement is

The definition of the high-stress region for application of Eqs. 5.5.3.2-1 and 5.5.3.2-2 for flexural reinforcement shall be taken as one-third of the span on each side of the section of maximum moment.

5.5.3.3—Prestressing Steel

The constant-amplitude fatigue threshold, $(\Delta F)_{TH}$, for prestressing steel shall be taken as:

- 18.0 ksi for radii of curvature in excess of 30.0 ft, and
- 10.0 ksi for radii of curvature not exceeding 12.0 ft.

A linear interpolation may be used for radii between 12.0 and 30.0 ft.

5.5.3.4—Welded or Mechanical Splices of Reinforcement

For welded or mechanical connections that are subject to repetitive loads, the constant-amplitude fatigue threshold, $(\Delta F)_{TH}$, shall be as given in Table 5.5.3.4-1.

Table 5.5.3.4-1—Constant-Amplitude Fatigue Threshold of Splices

Type of Splice	$(\Delta F)_{TH}$ for greater than 1,000,000 cycles
Grout-filled sleeve, with or without epoxy-coated bar	18.0 ksi
Cold-swaged coupling sleeves without threaded ends and with or without epoxy-coated bar; integrally-forged coupler with upset NC threads; steel sleeve with a wedge; one-piece taper-threaded coupler; and single V-groove direct butt weld	12.0 ksi
All other types of splices	4.0 ksi

Where the total cycles of loading, N , as specified in Eq. 6.6.1.2.5-2, are less than one million, $(\Delta F)_{TH}$ in Table 5.5.3.4-1 may be increased by the quantity $24(6 - \log N)$ ksi to a total not greater than the value given by Eq. 5.5.3.2-1 in Article 5.5.3.2. Higher values of $(\Delta F)_{TH}$, up to the value given by Eq. 5.5.3.2-1, may be used if justified by fatigue test data on splices that are the same as those that will be placed in service.

Welded splices shall not be used with ASTM A1035/A1035M reinforcement.

based on research by Hawkins et al. (1971), Hawkins and Takebe (1987), and Amom et al. (2007).

Since the fatigue provisions were developed based primarily on ASTM A615/A615M steel reinforcement, their applicability to other types of reinforcement is largely unknown.

C5.5.3.3

Where the radius of curvature is less than shown, or metal-to-metal fretting caused by prestressing tendons rubbing on hold-downs or deviations is apt to be a consideration, it will be necessary to consult the literature for more complete presentations that will allow the increased bending stress in the case of sharp curvature, or fretting, to be accounted for in the development of permissible fatigue stress ranges. Metal-to-metal fretting is not normally expected to be a concern in conventional pretensioned beams.

C5.5.3.4

Review of the available fatigue and static test data indicates that any splice that develops 125 percent of the yield strength of the bar will sustain one million cycles of a 4.0 ksi constant amplitude stress range. This lower limit is a close lower bound for the splice fatigue data obtained in NCHRP Project 10-35, and it also agrees well with the limit of 4.5 ksi for Category E from the provisions for fatigue of structural steel weldments. The strength requirements of Articles 5.10.8.4.2b and 5.10.8.4.2c also will generally ensure that a welded splice or mechanical connector will also meet certain minimum requirements for fabrication and installation, such as sound welding and proper dimensional tolerances. Splices that do not meet these requirements for fabrication and installation may have reduced fatigue performance. Further, splices designed to the lesser force requirements of Article 5.10.8.4.3b may not have the same fatigue performance as splices designed for the greater force requirement. Consequently, the minimum strength requirement indirectly provides for a minimum fatigue performance.

It was found in NCHRP Project 10-35 that there is substantial variation in the fatigue performance of different types of welds and connectors. However, all types of splices appeared to exhibit a constant amplitude fatigue limit for repetitive loading exceeding about one million cycles. The stress ranges for over one million cycles of loading given in Table 5.5.3.4-1 are based on statistical tolerance limits to constant amplitude staircase test data, such that there is a 95 percent level of confidence that 95 percent of the data would exceed the given values for five million cycles of loading. These values may, therefore, be regarded as a fatigue limit below which fatigue damage is unlikely to occur during the design lifetime of the structure. This is the same basis used to establish the fatigue design provisions for unspliced reinforcing bars in Article 5.5.3.2, which is based

on fatigue tests reported in NCHRP Report 164, *Fatigue Strength of High-Yield Reinforcing Bars*.

5.5.4—Strength Limit State

5.5.4.1—General

The strength limit state issues to be considered shall be those of strength and stability.

Factored resistance shall be the product of nominal resistance as determined in accordance with the applicable provisions of Articles 5.6, 5.7, 5.8, 5.9, 5.10, 5.11, 5.12, and 5.13, unless another limit state is specifically identified, and the resistance factor as specified in Article 5.5.4.2.

5.5.4.2—Resistance Factors

The provisions of this Article are applicable to prestressed concrete sections and to reinforced concrete sections with nonprestressed reinforcement having specified minimum yield strengths up to 100 ksi for elements and connections specified in Article 5.4.3.3. Where no distinction is made for density the values given shall be taken to apply to normal weight and lightweight concrete.

Resistance factor, ϕ , shall be taken as:

- For tension-controlled reinforced concrete sections as specified in Article 5.6.2.1:

normal weight concrete.....	0.90
lightweight concrete.....	0.90
- For tension-controlled prestressed concrete sections with bonded strand or tendons as specified in Article 5.6.2.1:

normal weight concrete.....	1.00
lightweight concrete.....	1.00
- For tension-controlled post-tensioned concrete sections with unbonded strand or tendons as specified in Article 5.6.2.1:

normal weight concrete.....	0.90
lightweight concrete.....	0.90
- For shear and torsion in reinforced concrete sections:

normal weight concrete.....	0.90
lightweight concrete.....	0.90
- For shear and torsion in monolithic prestressed concrete sections and prestressed concrete sections with cast-in-place closures or with match cast and epoxied joints having bonded strands or tendons:

normal weight concrete.....	0.90
lightweight concrete.....	0.90

C5.5.4.1

Additional resistance factors are specified in Article 12.5.5 for buried pipes and box structures made of concrete.

C5.5.4.2

In applying the resistance factors for tension-controlled and compression-controlled sections, the axial tensions and compressions to be considered are those caused by external forces. Effects of primary prestressing forces are not included.

In editions of and interims to the AASHTO *LRFD Bridge Design Specifications* prior to 2005, the provisions specified the magnitude of the resistance factor for cases of axial load or flexure, or both, in terms of the type of loading. For these cases, the ϕ -factor is now determined by the strain conditions at a cross-section, at nominal strength. The background and basis for these provisions are given in Mast (1992) and ACI 318-14.

A lower ϕ -factor is used for compression-controlled sections than is used for tension-controlled sections because compression-controlled sections have less ductility, are more sensitive to variations in concrete strength, and generally occur in members that support larger loaded areas than members with tension-controlled sections.

The use of debonded strand in a nontension-controlled zone qualifies for $\phi = 1.00$.

For sections subjected to axial load with flexure, factored resistances are determined by multiplying both P_n and M_n by the appropriate single value of ϕ . Compression-controlled and tension-controlled sections are specified in Article 5.6.2.1 as those that have net tensile strain in the extreme tension steel at nominal strength less than or equal to the compression-controlled strain limit, and equal to or greater than the tension-controlled strain limit, respectively. For sections with net tensile strain ϵ_t in the extreme tension steel at nominal resistance between the above limits, the value of ϕ may be determined by linear interpolation, as shown in Figure C5.5.4.2-1. The concept of net tensile strain ϵ_t is discussed in Article C5.6.2.1. Classifying sections as tension-controlled, transition or

- For shear and torsion in monolithic prestressed concrete sections and prestressed concrete sections with cast-in-place closures or with match cast and epoxied joints having unbonded strands or tendons:
 - normal weight concrete 0.85
 - lightweight concrete 0.85
- For compression-controlled sections with spirals, hoops, or ties, as specified in Article 5.6.2.1, except as specified in Articles 5.11.3 and 5.11.4.1.2 for Seismic Zones 2, 3, and 4 at the extreme event limit state 0.75
- For bearing on concrete 0.70
- For compression in strut-and-tie models 0.70
- For tension in strut-and-tie models:
 - reinforced concrete 0.90
 - prestressed concrete 1.00
- For compression in anchorage zones:
 - normal weight concrete 0.80
 - lightweight concrete 0.80
- For tension in steel in anchorage zones 1.00
- For resistance during pile driving 1.00

compression-controlled, and linearly varying, the resistance factor in the transition zone between reasonable values for the two extremes, provides a rational approach for determining ϕ and limiting the capacity of over-reinforced sections.

Figure C5.5.4.2-1—Variation of ϕ with Net Tensile Strain, ϵ_s , for Nonprestressed Reinforcement and for Prestressing Steel

For sections in which the net tensile strain in the extreme tension steel at nominal resistance is between the compression-controlled strain limit, ϵ_{cl} and tension-controlled strain limit, ϵ_{tl} , the value of ϕ associated with net tensile strain may be obtained by a linear interpolation from 0.75 to that for tension-controlled sections.

The ϕ -factor of 0.8 reflects the importance of the anchorage zone, the brittle failure mode for compression struts in the anchorage zone, and the relatively wide scatter of results of experimental anchorage zone studies.

The design of intermediate anchorages, anchorages, diaphragms, and multiple slab anchorages are addressed in Breen et al. (1994).

This variation, ϕ , may be computed for prestressed members such that:

$$0.75 \leq \phi = 0.75 + \frac{0.25(\epsilon_t - \epsilon_{cl})}{(\epsilon_{st} - \epsilon_{cl})} \leq 1.0 \quad (5.5.4.2-1)$$

and for nonprestressed members such that:

$$0.75 \leq \phi = 0.75 + \frac{0.15(\epsilon_t - \epsilon_{cl})}{(\epsilon_{st} - \epsilon_{cl})} \leq 0.9 \quad (5.5.4.2-2)$$

where:

- ϵ_t = net tensile strain in the extreme tension steel at nominal resistance (in./in.)
- ϵ_{cl} = compression-controlled strain limit in the extreme tension steel (in./in.)
- ϵ_{st} = tension-controlled strain limit in the extreme tension steel (in./in.)

Where combinations of different grades of nonprestressed reinforcement are used in design, the lowest resistance factor calculated for each grade of reinforcement shall be used.

Where the post-tensioning is a combination of bonded tendons and unbonded or debonded tendons, the resistance factor at any section shall be based on the bonding conditions for the tendons providing the majority of the prestressing force at the section.

Joints between precast units shall be either cast-in-place closures or match cast and epoxied joints. In selecting resistance factors for flexure, ϕ_f , and shear and torsion, ϕ_v , the bonding condition of the post-tensioning system shall be considered. In order for a tendon to be considered as bonded at a section, it should be fully developed at that section for a development length not less than that required by Article 5.9.4.3. Shorter embedment lengths may be permitted if demonstrated by full-size tests and approved by the Engineer.

5.5.4.3—Stability

The structure as a whole and its components shall be designed to resist sliding, overturning, uplift, and buckling. Effects of eccentricity of loads shall be considered in the analysis and design.

Buckling and stability of precast members during handling, transportation, and erection shall be investigated.

The typical cross-section of a continuous concrete box girder often has both conventional bar reinforcing and post-tensioning ducts. This superstructure, however, is first designed to satisfy the service limit state by determining the number of tendons required to satisfy allowable stress limits. Then, the strength limit state is checked. Nonprestressed reinforcement may or may not need to be added. If nonprestressed reinforcement is required to satisfy the strength but not the service limit state, the member is still considered prestressed for the purpose of determining the appropriate resistance factor.

Comprehensive tests of a large continuous three-span model of a twin-cell box girder bridge built from precast segments with bonded internal tendons and epoxy joints indicated that cracking was well distributed through the segment lengths. No epoxy joint opened at failure, and the load deflection curve was identical to that calculated for a monolithic specimen. The complete ultimate strength of the tendons was developed at failure. The model had substantial ductility and full development of calculated deflection at failure. Flexural cracking concentrated at joints and final failure came when a central joint opened widely and crushing occurred at the top of the joint.

C5.5.4.3

Stability during handling, transportation, and erection can govern the design of precast, prestressed girders. Precast members should be designed such that safe storage, handling, and erection can be accomplished by the contractor. This consideration does not make the designer responsible for the contractor's means and methods for construction, as discussed in Article 2.5.3.

Lateral bending stability analysis should be based on Precast Concrete Institute Publication CB-02-16-E, *Recommended Practice for Lateral Stability of Precast, Prestressed Concrete Bridge Girders*. A detailed design example is presented in Seguirant, Brice, and Khaleghi (2009).

5.5.5—Extreme Event Limit State**5.5.5.1—General**

The structure as a whole and its components shall be proportioned to resist collapse due to extreme events, specified in Table 3.4.1-1, as may be appropriate to its site and use.

5.5.5.2—Special Requirements for Seismic Zones 2, 3, and 4

A modified resistance factor for columns in Seismic Zones 2, 3, and 4 shall be taken as specified in Articles 5.11.3 and 5.11.4.1.2.

5.6—DESIGN FOR FLEXURAL AND AXIAL FORCE EFFECTS—B REGIONS

Reference to nonprestressed reinforcement in this article shall apply to steel with specified minimum yield strengths up to 100 ksi for elements and connections specified in Article 5.4.3.3.

5.6.1—Assumptions for Service and Fatigue Limit States

The following assumptions may be used in the design of reinforced and prestressed concrete components for all design concrete compressive strengths permitted by these specifications:

- Prestressed concrete resists tension at sections that are uncracked, except as specified in Article 5.6.6.
- The strains in the concrete vary linearly, except in components or regions of components for which conventional strength of materials is inappropriate.
- Where transformed section analysis is used to assess the elastic shortening at transfer or post-tensioning and elastic response due to transient loads in prestressed components, or the determination of elastic stresses in reinforced concrete components, the transformed area properties may be calculated by replacing the steel area with an equivalent concrete area equal to the steel area multiplied by a modular ratio, n , defined as:
 - E_s/E_c for reinforcing bars
 - E_p/E_c for prestressing tendons
- Where transformed section analysis is used to assess the time-dependent response to permanent loads, an age adjusted effective modular ratio that accounts for creep properties of concrete may be employed using the provisions of Article 5.4.2.3.2.

C5.6

Reinforcement with specified minimum yield strengths between 75.0 and 100 ksi may be used in seismic applications, with the Owner's approval, only as permitted in the *AASHTO Guide Specifications for LRFD Seismic Bridge Design* (2023).

C5.6.1

Prestressing is treated as part of resistance, except for anchorages and similar details, where the design is totally a function of the tendon force and for which a load factor is specified in Article 3.4.3. External reactions caused by prestressing induce force effects that normally are taken to be part of the loads side of Eq. 1.3.2.1-1. This represents a philosophical dichotomy. In lieu of more precise information, in these specifications the load factor for these induced force effects should be taken as that for the permanent loads.

Examples of components for which the assumption of linearly varying strains may not be suitable include deep components such as deep beams, corbels, and brackets.

Transformed section properties are used in the working stress methods based on elastic and time-dependent analysis, for instantaneous and creep effects, respectively. The methods are applicable for service and fatigue limit states. Approximate analysis using gross section properties may be adequate in some designs as long as volume change effects are recognized, and prestress losses are accounted for as specified in Article 5.9.3.

Where the applied load is constant over time, the age adjusted modulus of elasticity may be taken as the modulus of elasticity divided by one plus the creep coefficient given by Eq. 5.4.2.3.2-1. Using this method to include the effect of creep puts the emphasis on the material subject to creep as opposed to previous approaches that adjusted the steel rather than the concrete. It is also more consistent with Article 5.9.3.4.

5.6.2—Assumptions for Strength and Extreme Event Limit States

The following assumptions may be used for design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi.

5.6.2.1—General

Factored resistance of concrete components shall be based on the conditions of equilibrium and strain compatibility, the resistance factors as specified in Article 5.5.4.2, and the following assumptions:

- In components with bonded reinforcement or prestressing, or in the bonded length of debonded strands, strain is directly proportional to the distance from the neutral axis, except for deep members that shall satisfy the requirements for disturbed regions.
- In components with unbonded prestressing tendons, i.e., not debonded strands, the difference in strain between the tendons and the concrete section and the effect of deflections on tendon geometry are included in the determination of the stress in the tendons.
- If the concrete is unconfined, the maximum usable strain at the extreme concrete compression fiber is not greater than 0.003.
- If the concrete is confined, a maximum usable strain exceeding 0.003 in the confined core may be utilized if verified. Calculation of the factored resistance shall consider that the concrete cover may be lost at strains compatible with those in the confined concrete core.
- Except for the strut-and-tie model, the stress in the reinforcement is based on a stress-strain curve representative of the steel or on an approved mathematical representation, including development of reinforcement and prestressing elements and transfer of pretensioning.
- The tensile strength of the concrete is neglected.
- The concrete compressive stress-strain distribution is assumed to be rectangular, parabolic, or any other shape that results in a prediction of strength in substantial agreement with the test results.
- The development of reinforcement and prestressing elements and transfer of pretensioning are considered.
- Balanced strain conditions exist at a cross-section when tension reinforcement reaches the strain corresponding to its specified yield strength f_y just as the concrete in compression reaches its assumed ultimate strain of 0.003.
- Sections are compression-controlled where the net tensile strain in the extreme tension steel is equal to or less than the compression-controlled strain limit, ϵ_{cs} , at the time the concrete in compression reaches its assumed strain limit of 0.003. The compression-controlled strain limit is the net tensile strain in the

C5.6.2.1

The first paragraph of Article C5.6.1 applies.

The results of Rizkalla et al. (2007) have shown that the maximum usable strain at the extreme concrete compression fiber of 0.003 is valid for flexural members with design compressive strengths up to 18.0 ksi for normal weight concrete even though the provisions are currently limited to 15.0 ksi.

Research by Bae and Bayrak (2003) has shown that, for well-confined high-strength concrete (HSC) columns, the concrete cover may be lost at maximum usable strains at the extreme concrete compression fiber as low as 0.0022. The heavy confinement steel causes a weak plane between the concrete core and cover, causing high shear stresses and the resulting early loss of concrete cover.

The nominal flexural strength of a member is reached when the strain in the extreme compression fiber reaches the assumed strain limit of 0.003. The net tensile strain ϵ_t is the tensile strain in the extreme tension steel at nominal strength, exclusive of strains due to prestress, creep, shrinkage, and temperature. The net tensile strain in the extreme tension steel is determined from a linear strain distribution at nominal strength, as shown in Figure C5.6.2.1-1, using similar triangles.

reinforcement at balanced strain conditions. For nonprestressed reinforcement with a specified minimum yield strength of $f_y \leq 60.0$ ksi, ϵ_{cl} is taken as f_y/E_s but not greater than 0.002. For nonprestressed reinforcement with a specified minimum yield strength of 100 ksi, the compression-controlled strain limit may be taken as $\epsilon_{cl} = 0.004$. For nonprestressed reinforcement with a specified minimum yield strength between 60.0 and 100 ksi, the compression-controlled strain limit may be determined by linear interpolation based on specified minimum yield strength. For all prestressed reinforcement, the compression-controlled strain limit may be set equal to 0.002.

- Sections are tension-controlled where the net tensile strain in the extreme tension steel is equal to or greater than the tension-controlled strain limit, ϵ_{tl} , just as the concrete in compression reaches its assumed strain limit of 0.003. Sections with net tensile strain in the extreme tension steel between the compression-controlled strain limit and the tension-controlled strain limit constitute a transition region between compression-controlled and tension-controlled sections. The tension-controlled strain limit, ϵ_{tl} , shall be taken as 0.005 for nonprestressed reinforcement with a specified minimum yield strength, $f_y \leq 75.0$ ksi, and prestressed reinforcement. The tension-controlled strain limit, ϵ_{tl} , shall be taken as 0.008 for nonprestressed reinforcement with a specified minimum yield strength, $f_y = 100$ ksi. For nonprestressed reinforcement with a specified minimum yield strength between 75.0 and 100 ksi, the tension-controlled strain limit shall be determined by linear interpolation based on specified minimum yield strength.
- The use of compression reinforcement in conjunction with additional tension reinforcement is permitted to increase the strength of flexural members.

Figure C5.6.2.1-1—Strain Distribution and Net Tensile Strain

Where the net tensile strain in the extreme tension steel is sufficiently large (equal to or greater than the tension-controlled strain limit), the section is defined as tension-controlled where ample warning of failure with excessive deflection and cracking may be expected. Where the net tensile strain in the extreme tension steel is small (less than or equal to the compression-controlled strain limit), a brittle failure condition may be expected, with little warning of impending failure. Flexural members are usually tension-controlled, while compression members are usually compression-controlled. Some sections, such as those with small axial load and large bending moment, will have net tensile strain in the extreme tension steel between the above limits. These sections are in a transition region between compression- and tension-controlled sections. Article 5.5.4.2 specifies the appropriate resistance factors for tension-controlled and compression-controlled sections, and for intermediate cases in the transition region.

Before the development of these provisions, the limiting tensile strain for flexural members was not stated, but was implicit in the maximum reinforcement limit that was given as $c/d_e \leq 0.42$, which corresponded to a net tensile strain at the centroid of the tension reinforcement of 0.00414. The net tensile strain limit of 0.005 for tension-controlled sections was chosen to be a single value that applies to nonprestressed reinforcement with a specified minimum yield strength of 75.0 ksi or less and prestressed reinforcement. Research by Shahrooz et al. (2011) and Mast et al. (2008) supports the values stated for compression- and tension-controlled strain limits for steel with higher specified minimum yield strengths.

Unless unusual amounts of ductility are required, the tension-controlled strain limit will provide ductile behavior for most designs. One condition where greater ductile behavior is required is in design for redistribution of moments in continuous members and frames. Article 5.6.3.4 permits redistribution of negative moments. Since moment redistribution is dependent on adequate ductility in hinge regions, moment redistribution is limited to sections that have a net tensile strain of at least $1.5\epsilon_{cl}$.

For beams with compression reinforcement, or T-beams, the effects of compression reinforcement and

- In the approximate flexural resistance equations of Articles 5.6.3.1 and 5.6.3.2, f_y and f'_y may replace f_s and f'_s , respectively, subject to the following conditions:

- f_s may be replaced by f_y in the calculations in the cited articles as long as the resulting ratio c/d_s does not exceed:

$$\frac{c}{d_s} \leq \frac{0.003}{0.003 + \epsilon_{cl}} \quad (5.6.2.1-1)$$

where:

- c = distance from the extreme compression fiber to the neutral axis (in.)
- d_s = distance from extreme compression fiber to the centroid of the nonprestressed tensile reinforcement (in.)
- ϵ_{cl} = compression-controlled strain limit as specified above

If c/d_s exceeds this limit, strain compatibility shall be used to determine the stress in the nonprestressed tension reinforcement.

- f'_s may be replaced by f'_y in the calculations in the cited articles as long as $c \geq 3d'_s$ and $f_y \leq 60.0$ ksi. If $c < 3d'_s$ or $f_y > 60.0$ ksi, strain compatibility shall be used to determine the stress in the nonprestressed compression reinforcement. Alternatively, the compression reinforcement may be conservatively ignored, i.e., $A'_s = 0$.
- Where strain compatibility is used, the calculated stress in nonprestressed reinforcement having a specified minimum yield strength between 75.0 and 100 ksi shall not be taken as greater than the specified minimum yield strength.

Additional limitations on the maximum usable extreme concrete compressive strain in hollow rectangular compression members shall be investigated as specified in Article 5.6.4.7.

5.6.2.2—Rectangular Stress Distribution

The natural relationship between concrete stress and strain may be considered satisfied by an equivalent rectangular concrete compressive stress block of $\alpha_1 f'_c$ over a zone bounded by the edges of the cross-section and a straight line located parallel to the neutral axis at the distance $a = \beta_1 c$ from the extreme compression fiber. The distance c shall be measured perpendicular to the neutral axis. The stress block factor α_1 shall be taken as 0.85 for design compressive strengths of concrete not

flanges are automatically accounted for in the computation of net tensile strain, ϵ_t .

Where the approximate flexural resistance equations in Articles 5.6.3.1 and 5.6.3.2 are used, it is important to assure that both the nonprestressed tension and compression reinforcement are yielding to obtain accurate results. In previous editions of the AASHTO LRFD Bridge Design Specifications, the maximum reinforcement limit of $c/d_e \leq 0.42$ assured that the nonprestressed tension reinforcement would yield at nominal flexural resistance, but this limit was eliminated in the 2006 interim revisions. The current limit on c/d_s assures that the nonprestressed tension reinforcement will be at or near yield. The ratio $c \geq 3d'_s$ assures that nonprestressed compression reinforcement with $f_y \leq 60.0$ ksi will yield. For yield strengths above 60.0 ksi, the yield strain is close to or exceeds 0.003, so the compression steel may not yield. It is conservative to ignore the compression steel where calculating flexural resistance. In cases where either the tension or compression steel does not yield, it is more accurate to use a method based on the conditions of equilibrium and strain compatibility to determine the flexural resistance.

Values of the compression- and tension-controlled strain limits are given in Table C5.6.2.1-1 for common values of specified minimum yield strengths.

Table C5.6.2.1-1—Strain Limits for Nonprestressed Reinforcement

Specified Minimum Yield Strength, ksi	Strain Limits	
	Compression Control ϵ_{cl}	Tension Control ϵ_{tl}
60	0.0020	0.0050
75	0.0028	0.0050
80	0.0030	0.0056
100	0.0040	0.0080

The nonprestressed tension reinforcement limitation does not apply to prestressing steel used as tension reinforcement. The equations used to determine the stress in the prestressing steel at nominal flexural resistance already consider the effect of the depth to the neutral axis.

C5.6.2.2

For practical design, the rectangular compressive stress distribution defined in this article may be used in lieu of a more exact concrete stress distribution. This rectangular stress distribution does not represent the actual stress distribution in the compression zone at ultimate, but in many practical cases it does provide essentially the same results as those obtained in tests. All strength equations presented in Article 5.6.3 are based on the rectangular stress block.

exceeding 10.0 ksi. For design compressive strengths of concrete exceeding 10.0 ksi, α_1 shall be reduced at a rate of 0.02 for each 1.0 ksi of strength in excess of 10.0 ksi, except that α_1 shall not be taken to be less than 0.75. The stress block factor β_1 shall be taken as 0.85 for design compressive strengths of concrete not exceeding 4.0 ksi. For design compressive strengths of concrete exceeding 4.0 ksi, β_1 shall be reduced at a rate of 0.05 for each 1.0 ksi of strength in excess of 4.0 ksi, except that β_1 shall not be taken to be less than 0.65.

Additional limitations on the use of the rectangular stress block when applied to hollow rectangular compression members shall be investigated as specified in Article 5.6.4.7.

5.6.3—Flexural Members

The following assumptions may be used for design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi.

5.6.3.1—Stress in Prestressing Steel at Nominal Flexural Resistance

5.6.3.1.1—Components with Bonded Tendons

For rectangular or flanged sections subjected to flexure about one axis where the approximate stress distribution specified in Article 5.6.2.2 is used and for which f_{pe} is not less than $0.5 f_{pu}$, the average stress in prestressing steel, f_{ps} , may be taken as:

$$f_{ps} = f_{pu} \left(1 - k \frac{c}{d_p} \right) \quad (5.6.3.1.1-1)$$

in which:

$$k = 2 \left(1.04 - \frac{f_{py}}{f_{pu}} \right) \quad (5.6.3.1.1-2)$$

for T-section behavior:

$$c = \frac{A_{ps} f_{pu} + A_s f_s - A'_s f'_s - \alpha_1 f'_c (b - b_w) h_f}{\alpha_1 f'_c \beta_1 + k A_{ps} \frac{f_{pu}}{d_p}} \quad (5.6.3.1.1-3)$$

for rectangular section behavior:

Rizkalla et al. (2007) determine that α_1 gradually decreases for compressive strengths of concrete used in design in excess of 10.0 ksi.

The stress block factor β_1 is basically related to rectangular sections; however, for flanged sections in which the neutral axis is in the web, β_1 has experimentally been found to be an adequate approximation.

For sections that consist of a beam with a composite slab of different concrete strength, and the compression block includes both types of concrete, it is conservative to assume the composite beam to be of uniform strength at the lower of the concrete strengths in the flange and web. If a more refined estimate of flexural capacity is warranted, a more rigorous analysis method should be used. Examples of such analytical techniques are presented in Weigel, Seguirant, Brice, and Khaleghi (2003) and Seguirant, Brice, and Khaleghi (2005).

C5.6.3.1.1

Equations in this article and subsequent equations for flexural resistance are based on the assumption that the distribution of steel is such that it is reasonable to consider all of the nonprestressed tensile reinforcement to be lumped at the location defined by d_s and all of the prestressing steel can be considered to be lumped at the location defined by d_p . Therefore, in the case where a significant number of prestressing elements are on the compression side of the neutral axis, it is more appropriate to use a method based on the conditions of equilibrium and strain compatibility as indicated in Article 5.6.2.1. The background and basis for Eqs. 5.6.3.1.1-1 and 5.6.3.1.2-1 can be found in Loov (1988) and Naaman (1989; 1990; 1992).

Values of f_{py}/f_{pu} are defined in Table C5.6.3.1.1-1. Therefore, the values of k from Eq. 5.6.3.1.1-2 depend only on the type of tendon used.

Table C5.6.3.1.1-1—Values of k

Type of Tendon	f_{py}/f_{pu}	Value of k
Low relaxation strand	0.90	0.28
Type 1 high-strength bar	0.85	0.38
Type 2 high-strength bar	0.80	0.48

$$c = \frac{A_{ps}f_{pu} + A_s f_s - A'_s f'_s}{\alpha_1 f'_c \beta_1 b + k A_{ps} \frac{f_{pu}}{d_p}} \quad (5.6.3.1.1-4)$$

where:

- A_{ps} = area of prestressing steel (in.²)
- f_{pu} = specified tensile strength of prestressing steel (ksi)
- f_{py} = yield strength of prestressing steel (ksi)
- A_s = area of nonprestressed tension reinforcement (in.²)
- A'_s = area of compression reinforcement (in.²)
- f_s = stress in the nonprestressed tension reinforcement at nominal flexural resistance (ksi), as specified in Article 5.6.2.1
- f'_s = stress in the nonprestressed compression reinforcement at nominal flexural resistance (ksi), as specified in Article 5.6.2.1
- b = width of the compression face of the member; for a flange section in compression, the effective width of the flange, as specified in Article 4.6.2.6 (in.)
- b_w = web width or diameter of a circular section (in.)
- h_f = compression flange depth (in.)
- d_p = distance from extreme compression fiber to the centroid of the prestressing force (in.)
- c = distance from the extreme compression fiber to the neutral axis (in.)
- α_1 = stress block factor, specified in Article 5.6.2.2
- β_1 = stress block factor, specified in Article 5.6.2.2

5.6.3.1.2—Components with Unbonded Tendons

For rectangular or flanged sections subjected to flexure about one axis and for biaxial flexure with axial load as specified in Article 5.6.4.5, where the approximate stress distribution specified in Article 5.6.2.2 is used, the average stress in unbonded prestressing steel may be taken as:

$$f_{ps} = f_{pe} + 900 \left(\frac{d_p - c}{\ell_e} \right) \leq f_{py} \quad (5.6.3.1.2-1)$$

in which:

$$\ell_e = \left(\frac{2 \ell_i}{2 + N_s} \right) \quad (5.6.3.1.2-2)$$

for T-section behavior:

$$c = \frac{A_{ps} f_{ps} + A_s f_s - A'_s f'_s - \alpha_1 f'_c (b - b_w) h_f}{\alpha_1 f'_c \beta_1 b_w} \quad (5.6.3.1.2-3)$$

C5.6.3.1.2

A first estimate of the average stress in unbonded prestressing steel may be made as:

$$f_{ps} = f_{pe} + 15.0 \text{ (ksi)} \quad (C5.6.3.1.2-1)$$

In order to solve for the value of f_{ps} in Eq. 5.6.3.1.2-1, the equation of force equilibrium at ultimate is needed. Thus, two equations with two unknowns (f_{ps} and c) need to be solved simultaneously to achieve a closed-form solution.

for rectangular section behavior:

$$c = \frac{A_{ps}f_{ps} + A_sf_s - A'_sf'_s}{\alpha_1f'_c\beta_1b} \quad (5.6.3.1.2-4)$$

where:

- c = distance from extreme compression fiber to the neutral axis assuming the tendon prestressing steel has yielded, given by Eqs. 5.6.3.1.2-3 and 5.6.3.1.2-4 for T-section behavior and rectangular section behavior, respectively (in.)
- ℓ_e = effective tendon length (in.)
- ℓ_i = length of tendon between anchorages (in.)
- N_s = number of plastic hinges at supports in an assumed failure mechanism crossed by the tendon between anchorages or discretely bonded points assumed as:
- For simple spans.....0
 - End spans of continuous units.....1
 - Interior spans of continuous units.....2
- f_{py} = yield strength of prestressing steel (ksi)
- f_{pe} = effective stress in prestressing steel (ksi)

5.6.3.1.3—Components with Both Bonded and Unbonded Tendons

5.6.3.1.3a—Detailed Analysis

Except as specified in Article 5.6.3.1.3b for components with both bonded and unbonded tendons, the stress in the prestressing steel shall be computed by detailed analysis. This analysis shall take into account the strain compatibility between the section and the bonded prestressing steel. The stress in the unbonded prestressing steel shall take into account the global displacement compatibility between bonded sections of tendons located within the span. Bonded sections of unbonded tendons may be anchorage points and any bonded section, such as deviators. Consideration of the possible slip at deviators shall be taken into consideration. The nominal flexural strength should be computed directly from the stresses resulting from this analysis.

5.6.3.1.3b—Simplified Analysis

In lieu of the detailed analysis described in Article 5.6.3.1.3a, the stress in the unbonded tendons may be conservatively taken as the effective stress in the prestressing steel, f_{pe} . In this case, the stress in the bonded prestressing steel shall be computed using Eqs. 5.6.3.1.1-1 through 5.6.3.1.1-4, with the term $A_{ps}f_{pu}$ in Eqs. 5.6.3.1.1-3 and 5.6.3.1.1-4 replaced with the term $A_{psb}f_{pu} + A_{psu}f_{pe}$.

where:

- $$\begin{aligned} A_{psb} &= \text{area of bonded prestressing steel (in.}^2\text{)} \\ A_{psu} &= \text{area of unbonded prestressing steel (in.}^2\text{)} \end{aligned}$$

When computing the nominal flexural resistance using Eq. 5.6.3.2.2-1, the average stress in the prestressing steel shall be taken as the weighted average of the stress in the bonded and unbonded prestressing steel, and the total area of bonded and unbonded prestressing shall be used.

5.6.3.2—Flexural Resistance

5.6.3.2.1—Factored Flexural Resistance

The factored flexural resistance, M_r , shall be taken as:

$$M_r = \phi M_n \quad (5.6.3.2.1-1)$$

where:

M_n = nominal flexural resistance (kip-in.)
 ϕ = resistance factor as specified in Article 5.5.4.2

5.6.3.2.2—Flanged Sections

For flanged sections subjected to flexure about one axis and for biaxial flexure with axial load as specified in Article 5.6.4.5, where the approximate stress distribution specified in Article 5.6.2.2 is used and where the compression flange depth is less than $a = \beta_1 c$, as determined in accordance with Eqs. 5.6.3.1.1-3, 5.6.3.1.1-4, 5.6.3.1.2-3, or 5.6.3.1.2-4, the nominal flexural resistance may be taken as:

$$M_n = A_{ps} f_{ps} \left(d_p - \frac{a}{2} \right) + A_s f_s \left(d_s - \frac{a}{2} \right) - A'_s f'_s \left(d'_s - \frac{a}{2} \right) + \alpha_1 f'_c (b - b_w) h_f \left(\frac{a}{2} - \frac{h_f}{2} \right) \quad (5.6.3.2.2-1)$$

where:

A_{ps} = area of prestressing steel (in.²)
 f_{ps} = average stress in prestressing steel at nominal bending resistance specified in Eq. 5.6.3.1.1-1 (ksi)
 d_p = distance from extreme compression fiber to the centroid of prestressing tendons (in.)
 A_s = area of nonprestressed tension reinforcement (in.²)
 f_s = stress in the nonprestressed tension reinforcement at nominal flexural resistance (ksi), as specified in Article 5.6.2.1
 d_s = distance from extreme compression fiber to the centroid of nonprestressed tensile reinforcement (in.)
 A'_s = area of compression reinforcement (in.²)

C5.6.3.2.1

Moment at the face of the support may be used for design. Where fillets making an angle of 45 degrees or more with the axis of a continuous or restrained member are built monolithic with the member and support, the face of support should be considered at a section where the combined depth of the member and fillet is at least one and one-half times the thickness of the member. No portion of a fillet should be considered as adding to the effective depth when determining the nominal resistance.

C5.6.3.2.2

In previous editions and interims of the AASHTO *LRFD Bridge Design Specifications*, the stress block factor, β_1 , was applied to the flange overhang term of Eqs. 5.6.3.1.1-3, 5.6.3.1.2-3, and 5.6.3.2.2-1. This was not consistent with the original derivation of the equivalent rectangular stress block as it applies to flanged sections (Mattock, Kriz, and Hognestad, 1961). The β_1 factor has been removed from the flange overhang term of these equations. For additional information see Mattock, Kriz, and Hognestad (1961), Seguirant (2002); Girgis, Sun, and Tadros (2002); Naaman (2002); Weigel, Seguirant, Brice, and Khaleghi (2003); Baran, Schultz, and French (2005); and Seguirant, Brice, and Khaleghi (2005).

- f'_s = stress in the nonprestressed compression reinforcement at nominal flexural resistance (ksi), as specified in Article 5.6.2.1
- d'_s = distance from extreme compression fiber to the centroid of compression reinforcement (in.)
- f'_c = design concrete compressive strength (ksi)
- α_1 = stress block factor, specified in Article 5.6.2.2
- b = width of the compression face of the member; for a flange section in compression, the effective width of the flange, as specified in Article 4.6.2.6 (in.)
- b_w = web width or diameter of a circular section (in.)
- β_1 = stress block factor, specified in Article 5.6.2.2
- h_f = compression flange depth of an I- or T-member (in.)
- a = $c\beta_1$; depth of the equivalent stress block (in.)

5.6.3.2.3—Rectangular Sections

For rectangular sections subjected to flexure about one axis and for biaxial flexure with axial load as specified in Article 5.6.4.5, where the approximate stress distribution specified in Article 5.6.2.2 is used and where the compression flange depth is not less than $a = \beta_1 c$ as determined in accordance with Eqs. 5.6.3.1.1-4 or 5.6.3.1.2-4, the nominal flexural resistance M_n may be determined by using Eqs. 5.6.3.1.1-1 through 5.6.3.2.2-1, in which case b_w shall be taken as b .

5.6.3.2.4—Other Cross-Sections

For cross-sections other than flanged or essentially rectangular sections with vertical axis of symmetry or for sections subjected to biaxial flexure without axial load, the nominal flexural resistance, M_n , shall be determined by an analysis based on the assumptions specified in Article 5.6.2. The requirements of Article 5.6.3.3 shall apply.

5.6.3.2.5—Strain Compatibility Approach

Alternatively, the strain compatibility approach may be used if more precise calculations are required. The appropriate provisions of Article 5.6.2.1 shall apply.

The stress and corresponding strain in any given layer of reinforcement may be taken from any representative stress-strain formula or graph for nonprestressed reinforcement and prestressing strands. Minimum specified properties shall be used in the stress-strain formula or graph for nonprestressed reinforcement with yield strengths between 75.0 and 100 ksi.

5.6.3.2.6—Composite Girder Sections

For composite girder sections in which the neutral axis is located below the deck and within the prestressed high-strength concrete girder, the nominal flexural

C5.6.3.2.6

Test results from Rizkalla et al. (2007) show that, in lieu of detailed analysis with two different compressive strengths of concrete used in design in the compression

resistance, M_n , may be determined by Eq. 5.6.3.2.2-1, based on the concrete compressive strength of the deck.

5.6.3.3—Minimum Reinforcement

Unless otherwise specified, at any section of a noncompression-controlled flexural component, the amount of prestressed and nonprestressed tensile reinforcement shall be adequate to develop a factored flexural resistance, M_r , greater than or equal to the lesser of the following:

- 1.33 times the factored moment required by the applicable strength load combination specified in Table 3.4.1-1;

- $$M_{cr} = \gamma_3 \left[(\gamma_1 f_r + \gamma_2 f_{cpe}) S_c - M_{dnc} \left(\frac{S_c}{S_{nc}} - 1 \right) \right]$$
 (5.6.3.3-1)

where:

- M_{cr} = cracking moment (kip-in.)
 f_r = modulus of rupture of concrete, specified in Article 5.4.2.6
 f_{cpe} = compressive stress in concrete due to effective prestress forces only (after allowance for all prestress losses) at extreme fiber of section where tensile stress is caused by externally applied loads (ksi)
 S_c = section modulus for the extreme fiber of the composite section where tensile stress is caused by externally applied loads (in.³)
 M_{dnc} = total unfactored dead load moment acting on the monolithic or noncomposite section (kip-in.)
 S_{nc} = section modulus for the extreme fiber of the monolithic or noncomposite section where tensile stress is caused by externally applied loads (in.³)

Appropriate values for M_{dnc} and S_{nc} shall be used for any intermediate composite sections. Where the beams are designed for the monolithic or noncomposite section to resist all loads, S_{nc} shall be substituted for S_c in Eq. 5.6.3.3-1 for the calculation of M_{cr} .

The following factors shall be used to account for variability in the flexural cracking strength of concrete, variability of prestress, and the ratio of nominal yield stress of reinforcement to ultimate:

- γ_1 = flexural cracking variability factor
 = 1.2 for precast segmental structures
 = 1.6 for all other concrete structures
 γ_2 = prestress variability factor
 = 1.1 for bonded tendons
 = 1.0 for unbonded tendons

zone, the use of lower concrete compressive strength of the deck provides a sufficiently accurate yet conservative estimate of the nominal flexural resistance.

C5.6.3.3

Minimum reinforcement provisions are intended to reduce the probability of brittle failure by providing flexural capacity greater than the cracking moment.

The sources of variability in computing the cracking moment and resistance are appropriately factored (Holombo and Tadros, 2009). The factor applied to the modulus of rupture, γ_1 , is greater than the factor applied to the amount of prestress, γ_2 , to account for greater variability.

For precast segmental construction, cracking generally starts at the segment joints. Research at the University of California, San Diego has shown that flexure cracks occur adjacent to the epoxy-bonded match-cast face, where the accumulation of fines reduces the tensile strength (Megally et al., 2003). Based on this observation, a reduced γ_1 factor of 1.2 is justified.

- γ_3 = ratio of specified minimum yield strength to ultimate tensile strength of the nonprestressed reinforcement
- = 0.67 for AASHTO M 31M/M 31 (ASTM A615/A615M), Grade 60 reinforcement
 - = 0.75 for AASHTO M 31 M/M 31 (ASTM A615/A615M), Grade 75 reinforcement
 - = 0.76 for AASHTO M 31 M/M 31 (ASTM A615/A615M), Grade 80 reinforcement
 - = 0.75 for ASTM A706/A706M, Grade 60 reinforcement
 - = 0.80 for ASTM A706/A706M, Grade 80 reinforcement
 - = 0.67 for AASHTO M 334M/M 334 (ASTM A1035/A1035M), Grade 100 reinforcement

For prestressing steel, γ_3 shall be taken as 1.0.

The provisions of Article 5.10.6 shall apply.

5.6.3.4—Moment Redistribution

In lieu of more refined analysis, where bonded reinforcement that satisfies the provisions of Article 5.10.8 is provided at the internal supports of continuous spans, negative moments determined by elastic theory at strength limit states may be increased or decreased by not more than 1000 ϵ_t percent, with a maximum of 20 percent. Redistribution of negative moments shall be made only where ϵ_t is equal to or greater than 1.5 ϵ_{tl} at the section at which moment is reduced, where ϵ_{tl} is the tension-controlled strain limit specified in Article 5.6.2.1.

Positive moments shall be adjusted to account for the changes in negative moments to maintain equilibrium of loads and force effects.

5.6.3.5—Deformations

5.6.3.5.1—General

The provisions of Article 2.5.2.6 shall be considered.

Deck joints and bearings shall accommodate the dimensional changes caused by loads, creep, shrinkage, thermal changes, settlement, and prestressing.

Testing of a large number of lightly reinforced and prestressed concrete members at the University of Illinois demonstrated that significant inelastic displacements can be achieved, and none of the beams tested failed without large warning deflections (Freyermuth and Aalami, 1997). If these experiments were conducted in load control, a number of specimens would have failed without warning because the ultimate strength (including the effects of strain hardening) was less than the cracking strength. Based on this observation, the ultimate strength should be used instead of the nominal strength as a true measure of brittle response. The ratio of steel stress at yield to ultimate γ_3 sufficiently approximates the nominal to ultimate strength for lightly reinforced concrete members.

C5.6.3.4

In editions and interims to the AASHTO *LRFD Bridge Design Specifications* prior to 2005, Article 5.6.3.4 specified the permissible redistribution percentage in terms of the c/d_e ratio. The current specification specifies the permissible redistribution percentage in terms of net tensile strain ϵ_t .

Mast (1992) provides an equation for the minimum strain in the tensile steel required for moment redistribution, which is based on the yield strain of the reinforcing steel and the assumption that $\rho/\rho_{bal} = 0.5$. Using reasonable values of yield strain for reinforcement with $f_y = 100$ ksi, the minimum tensile strain for moment redistribution can be found as 0.012, which is 1.5 ϵ_{tl} (Shahrooz et al., 2011). Previous versions of this article set the minimum tensile strain at 0.0075 where the tension-controlled strain limit was set to 0.005. Thus, 1.5 ϵ_{tl} gives the same value of minimum tensile strain for moment redistribution for reinforcement with $f_y \leq 75.0$ ksi as in previous editions, but also provides a reasonable value of minimum tensile strain for moment redistribution for higher strength reinforcement.

C5.6.3.5.1

For more precise determinations of long-term deflections, the creep and shrinkage coefficients cited in Article 5.4.2.3 should be utilized. These coefficients include the effects of aggregate characteristics, humidity at the structure site, relative thickness of member, maturity at time of loading, and length of time under loads.

5.6.3.5.2—Deflection and Camber

Deflection and camber calculations shall consider appropriate combinations of dead load, live load, prestress forces, erection loads, concrete creep and shrinkage, and steel relaxation.

For determining deflection and camber, the provisions of Articles 4.5.2.1, 4.5.2.2, and 5.9.3.6 shall apply.

C5.6.3.5.2

For nonprestressed members, camber can be built into a member to compensate for dead load deflection and to achieve the desired roadway geometry. Natural camber in prestressed members comes from the eccentricity of prestressing and amount of the camber depends on the prestress force and profile. In some situations, precamber can be built into the girder formwork, which can add to or reduce the natural camber from the prestressing. The introduction of this precamber allows prestressed concrete girders to follow the roadway vertical alignment within tolerances associated with the natural camber, which would reduce applied dead loads from concrete buildup and maximize the below vertical clearance by maintaining the superstructure depth fairly constant along the span.

For structures such as segmentally constructed bridges, camber calculations should be based on the modulus of elasticity and the maturity of the concrete when each increment of load is added or removed, as specified in Articles 5.4.2.3 and 5.12.5.3.6.

5.6.3.5.2a—Instantaneous Deflections

For nonprestressed members, unless obtained by a more comprehensive analysis, instantaneous deflections shall be calculated using the modulus of elasticity for concrete as specified in Article 5.4.2.4, and the effective moment of inertia, I_e , calculated in accordance with Table 5.6.3.5.2a-1:

C5.6.3.5.2a

The effective moment of inertia approximation, developed by Bischoff and Scanlon (2008), has been shown to result in calculated deflections that have sufficient accuracy for a wide range of reinforcement ratios. M_{cr} is multiplied by 2/3 to consider restraint that can reduce the effective cracking moment as well as to account for reduced tensile strength of early-age concrete that can lead to cracking during construction.

Previous editions of the AASHTO LRFD Bridge Design Specifications used a different equation to calculate I_e . The previous equation did not consider the effects of restraint, and has subsequently been shown to underestimate deflections for members with low reinforcement ratios. For members with greater than 1 percent longitudinal tension reinforcement and a service moment at least twice the cracking moment, there is little difference between deflections calculated using the former and the current provisions.

Table 5.6.3.5.2a-1—Effective Moment of Inertia, I_e

Service Moment	Effective Moment of Inertia, I_e (in. ⁴)
$M_a \leq \frac{2}{3} M_{cr}$	I_g
$M_a > \frac{2}{3} M_{cr}$	$\frac{I_{cr}}{1 - \left(\frac{\frac{2}{3} M_{cr}}{M_a} \right)^2 \left(1 - \frac{I_{cr}}{I_g} \right)}$

in which:

$$M_{cr} = f_r \frac{I_g}{y_t} \quad (5.6.3.5.2a-1)$$

where:

- M_{cr} = cracking moment (kip-in.)
- M_a = maximum moment in a component due to service loads at the stage for which deformation is computed (kip-in.)
- I_g = moment of inertia of the gross concrete section about the centroidal axis, neglecting the reinforcement (in.⁴)

- I_{cr} = moment of inertia of the cracked section, transformed to concrete (in.⁴)
- f_r = modulus of rupture of concrete as specified in Article 5.4.2.6 (ksi)
- y_t = distance from the centroidal axis of the gross section to the extreme fiber in tension (in.)

For prismatic members, effective moment of inertia shall be taken as the value obtained from Table 5.6.3.5.2a-1 at midspan for simple or continuous spans, and at the support for cantilevers. For continuous nonprismatic members, the effective moment of inertia shall be taken as the average of the values obtained from Table 5.6.3.5.2a-1 for the critical positive and negative moment sections.

For prestressed members meeting the tensile stress limits of Article 5.9.2.3.2b, instantaneous deflections may be calculated based on I_g .

5.6.3.5.2b—Time-Dependent Deflections

For nonprestressed members, unless obtained from a more comprehensive analysis, additional time-dependent deflection resulting from creep and shrinkage of flexural members shall be calculated as the product of the immediate deflection caused by sustained load and the factor, λ_s :

$$\lambda_s = \frac{\xi}{1 + 50\rho'} \quad (5.6.3.5.2b-1)$$

where:

$$\rho' = \frac{A'_s}{bd}$$

- A'_s = area of compression reinforcement (in.²)
- b = width of compression face of member (in.)
- d = effective depth of the member (in.)
- ξ = time-dependent factor for sustained loads, in accordance with Table 5.6.3.5.2b-1

Table 5.6.3.5.2b-1—Time-Dependent Factor for Sustained Loads

Sustained Load Duration (months)	Time-Dependent Factor, ξ
3	1.0
6	1.2
12	1.4
60 or more	2.0

C5.6.3.5.2b

Shrinkage and creep cause time-dependent deflections in addition to the instantaneous deflections that occur when sustained loads are first placed on the structure. Instantaneous and time-dependent deflections are additive in determining the total deflection. Such deflections are influenced by temperature, humidity, curing conditions, age at time of loading, amount of compression reinforcement, and magnitude of the sustained load. The expression given in this section is considered satisfactory for use with the calculation procedure for instantaneous deflections provided in Article 5.6.3.5.2a, and with the limits given in Article 2.5.2.6.2. The deflection calculated in accordance with this section is the additional time-dependent deflection due to the dead load and those portions of other loads that will be sustained for a sufficient period to cause significant time-dependent deflections.

Eq. 5.6.3.5.2b-1 was developed in Branson (1971). In Eq. 5.6.3.5.2b-1, the term $(1 + 50\rho')$ accounts for the effect of compression reinforcement in reducing time-dependent deflections. $\xi = 2.0$ represents a nominal time-dependent factor for a five-year duration of loading.

Calculation of time-dependent deflections of prestressed concrete flexural members is challenging. The time-dependent deflection is usually based on mix-specific data in combination with creep and shrinkage characteristics, which the calculation procedures are described in Article 5.4.2.3. Other suitable methods for calculating time-dependent deflections of prestressed members that consider all effects, such as those found in Rosa et al. (2007) and PCI (2014; 2017), may also be used.

In Eq. 5.6.3.5.2b-1, ρ' is calculated at midspan for simple and continuous spans, and at the support for cantilevers.

Additional time-dependent deflection of prestressed concrete members shall be calculated considering stresses in concrete and reinforcement under sustained load, and the effects of creep and shrinkage of concrete and relaxation of prestressed reinforcement.

The contract documents shall require that deflections of segmentally constructed bridges shall be calculated prior to casting of segments based on the anticipated casting and erection schedules and that they shall be used as a guide against which actual deflection measurements are checked.

The contract documents shall require that deflections of segmentally constructed bridges shall be calculated prior to casting of segments based on the anticipated casting and erection schedules and that they shall be used as a guide against which actual deflection measurements are checked.

5.6.3.5.3—Axial Deformation

Instantaneous shortening or expansion due to loads shall be determined using the modulus of elasticity of the materials at the time of loading.

Instantaneous shortening or expansion due to temperature shall be determined in accordance with Articles 3.12.2, 3.12.3, and 5.4.2.2.

Long-term shortening due to shrinkage and creep shall be determined as specified in Article 5.4.2.3.

5.6.4—Compression Members

5.6.4.1—General

Unless otherwise permitted, compression members shall be analyzed with consideration of the effects of:

- eccentricity,
- axial loads,
- variable moments of inertia,
- degree of end fixity,
- deflections,
- duration of loads, and
- prestressing.

In lieu of a refined procedure, nonprestressed columns with the slenderness ratio, $K\ell_u/r < 100$, may be designed by the approximate procedure specified in Article 5.6.4.3.

where:

- K = effective length factor for compression members, specified in Article 4.6.2.5
- ℓ_u = unbraced length (in.)
- r = radius of gyration of gross cross-section (in.)

The requirements of this article shall be supplemented and modified for structures in Seismic Zones 2, 3, and 4, as specified in Article 5.11.

Provisions shall be made to transfer all force effects from compression components, adjusted for second-order moment magnification, to adjacent components.

Where the connection to an adjacent component is by a concrete hinge, longitudinal reinforcement shall be centralized within the hinge to minimize flexural resistance and shall be developed on both sides of the hinge.

5.6.4.2—Limits for Reinforcement

C5.6.4.2

The following reinforcement limits may be used for design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi.

Additional limits on reinforcement for compression members in Seismic Zones 2, 3, and 4 shall be considered as specified in Articles 5.11.3 and 5.11.4.1.1.

The maximum area of prestressed and nonprestressed longitudinal reinforcement for noncomposite compression components shall satisfy the following:

$$\frac{A_s}{A_g} + \frac{A_{ps} f_{pu}}{A_g f_y} \leq 0.08 \quad (5.6.4.2-1)$$

and the area of prestressed longitudinal reinforcement shall also satisfy the following:

$$\frac{A_{ps} f_{pe}}{A_g f'_c} \leq 0.30 \quad (5.6.4.2-2)$$

Except as specified herein, the minimum area of prestressed and nonprestressed longitudinal reinforcement for noncomposite compression components shall satisfy the following:

$$\frac{A_s}{A_g} + \frac{A_{ps} f_{pu}}{A_g f_y} \geq 0.135 \frac{f'_c}{f_y} \quad (5.6.4.2-3)$$

Where the unfactored permanent loads do not exceed $0.4 A_g f'_c$, the reinforcement ratio calculated by Eq. 5.6.4.2-3 need not be greater than:

$$\frac{A_s}{A_g} + \frac{A_{ps} f_{pu}}{A_g f_y} \leq 0.015 \quad (5.6.4.2-4)$$

where:

A_s = area of nonprestressed tension reinforcement (in.²)

A_g = gross area of section (in.²)

A_{ps} = area of prestressing steel (in.²)

According to current American Concrete Institute (ACI) codes (ACI 318), the area of longitudinal reinforcement for nonprestressed noncomposite compression components should be not less than $0.01 A_g$. Analyses by Rizkalla et al. (2007) showed that the reinforcement ratio calculated by Eq. 5.6.4.2-3 need not be greater than 0.015 for the condition indicated, which is typically the case encountered in design. The limit of 0.015 is based on a reinforcement yield strength of 60.0 ksi and is applicable for specified yield strengths of 60.0 ksi and greater. For prestressed members, current codes specify a minimum average prestress of 0.225 ksi. Here also the influence of the design concrete compressive strength is not accounted for. A design compressive strength of concrete of 5.0 ksi was used as a basis for these provisions, and a weighted averaging procedure was used to arrive at the equation.

- For members braced against sidesway, the effective length factor, K , is taken as 1.0, unless it is shown by analysis that a lower value may be used.
- For members not braced against sidesway, K is determined with due consideration for the effects of cracking and reinforcement on relative stiffness and is taken as not less than 1.0.

In lieu of a more precise calculation, EI for use in determining P_e , as specified in Eq. 4.5.3.2.2b-5, shall be determined as the larger of the following:

$$EI = \frac{\frac{E_c I_g}{5} + E_s I_s}{1 + \beta_d} \quad (5.6.4.3-1)$$

$$EI = \frac{\frac{E_c I_g}{2.5}}{1 + \beta_d} \quad (5.6.4.3-2)$$

where:

- EI = flexural stiffness (kip-in.²)
 E_c = modulus of elasticity of concrete (ksi)
 I_g = moment of inertia of the gross concrete section about the centroidal axis, neglecting the reinforcement (in.⁴)
 E_s = modulus of elasticity of longitudinal steel (ksi)
 I_s = moment of inertia of longitudinal reinforcement about the centroidal axis (in.⁴)
 β_d = ratio of maximum factored permanent load moments to maximum factored total load moment; always positive

For eccentrically prestressed members, consideration shall be given to the effect of lateral deflection due to prestressing in determining the magnified moment.

5.6.4.4—Factored Axial Resistance

The following assumptions may be used for design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi.

The factored axial resistance of concrete compressive components, symmetrical about both principal axes, shall be taken as:

$$P_r = \phi P_n \quad (5.6.4.4-1)$$

in which:

- For members with spiral or hoop reinforcement with closure made using a full-welded splice, a full-mechanical coupler, or by overlapping with hooks around longitudinal reinforcement:

C5.6.4.4

The values of 0.85 and 0.80 in Eqs. 5.6.4.4-2 and 5.6.4.4-3 place upper limits on the usable resistance of compression members to allow for unintended eccentricity.

In the absence of concurrent bending due to external loads or eccentric application of prestress, the ultimate strain on a compression member is constant across the entire cross-section. Prestressing causes compressive stresses in the concrete, which reduces the resistance of compression members to externally applied axial loads. The term, $E_p \epsilon_{cu}$, accounts for the fact that a column or pile also shortens under externally applied loads, which serves to reduce the level of compression due to prestress. Assuming a concrete compressive strain at ultimate, $\epsilon_{cu} = 0.003$, and a prestressing steel modulus,

$$P_n = 0.85 \left[\frac{k_c f'_c (A_g - A_{st} - A_{ps}) + f_y A_{st}}{-A_{ps} (f_{pe} - E_p \epsilon_{cu})} \right] \quad (5.6.4.4-2)$$

- For members with tie reinforcement or hoop reinforcement with closure made using a lap splice:

$$P_n = 0.80 \left[\frac{k_c f'_c (A_g - A_{st} - A_{ps}) + f_y A_{st}}{-A_{ps} (f_{pe} - E_p \epsilon_{cu})} \right] \quad (5.6.4.4-3)$$

The factor, k_c , shall be taken as 0.85 for design compressive strengths not exceeding 10.0 ksi. For design compressive strengths exceeding 10.0 ksi, k_c shall be reduced at a rate of 0.02 for each 1.0 ksi of strength in excess of 10.0 ksi, except that k_c shall not be less than 0.75.

where:

- P_r = factored axial resistance, with or without flexure (kip)
- ϕ = resistance factor, specified in Article 5.5.4.2
- P_n = nominal axial resistance, with or without flexure (kip)
- k_c = ratio of the maximum concrete compressive stress to the design compressive strength of concrete
- f'_c = compressive strength of concrete for use in design (ksi)
- A_g = gross area of section (in.²)
- A_{st} = total area of longitudinal nonprestressed reinforcement (in.²)
- A_{ps} = area of prestressing steel (in.²)
- f_y = specified minimum yield strength of reinforcement (ksi)
- f_{pe} = effective stress in prestressing steel (ksi)
- E_p = modulus of elasticity of prestressing steel (ksi)
- ϵ_{cu} = failure strain of concrete in compression (in./in.)

5.6.4.5—Biaxial Flexure

The following assumptions may be used for design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi.

In lieu of an analysis based on equilibrium and strain compatibility for biaxial flexure, noncircular members subjected to biaxial flexure and compression may be proportioned using the following approximate expressions:

- If the factored axial load is greater than or equal to $0.10 \phi f'_c A_g$:

$E_p = 28,500$ ksi, gives a relatively constant value of 85.0 ksi for the amount of this reduction. Therefore, it is acceptable to reduce the effective prestressing by this amount. Conservatively, this reduction can be ignored.

Shahrooz et al. (2011) and Ward (2009) show that these provisions are applicable to columns using reinforcement with specified minimum yield strengths up to 100 ksi. Designers should account for the fact that columns using high-strength reinforcement may have smaller areas of steel or smaller gross dimensions for the same resistance, or both. These reductions may affect axial deformations, slenderness effects, and the effects of creep and shrinkage.

C5.6.4.5

Eqs. 5.6.3.2.1-1 and 5.6.4.4-1 relate factored resistances, given in Eqs. 5.6.4.5-1 and 5.6.4.5-2 by the subscript r , e.g., M_{rx} , to the nominal resistances and the resistance factors. Thus, although the AASHTO Standard Specifications included the resistance factor explicitly in equations corresponding to Eqs. 5.6.4.5-1 and 5.6.4.5-2, these specifications implicitly include the resistance factor by using factored resistances in the denominators.

$$\frac{1}{P_{rx}} = \frac{1}{P_{rx}} + \frac{1}{P_{ry}} - \frac{1}{\phi P_o} \quad (5.6.4.5-1)$$

in which:

$$P_o = k_c f'_c (A_g - A_{st} - A_{ps}) + f_y A_{st} - A_{ps} (f_{pe} - E_p \epsilon_{cu}) \quad (5.6.4.5-2)$$

- If the factored axial load is less than $0.10 \phi f'_c A_g$:

$$\frac{M_{ux}}{M_{rx}} + \frac{M_{uy}}{M_{ry}} \leq 1.0 \quad (5.6.4.5-3)$$

where:

- P_{rx} = factored axial resistance in biaxial flexure (kip)
- P_{rx} = factored axial resistance determined on the basis that only eccentricity e_x is present (kip)
- P_{ry} = factored axial resistance determined on the basis that only eccentricity e_y is present (kip)
- ϕ = resistance factor for members in axial compression
- P_o = nominal axial resistance of a section at 0.0 eccentricity (kip)
- P_u = factored applied axial force (kip)
- k_c = ratio of the maximum concrete compressive stress to the design compressive strength of concrete
- M_{ux} = factored applied moment about the x -axis (kip-in.)
- M_{uy} = factored applied moment about the y -axis (kip-in.)
- M_{rx} = uniaxial factored flexural resistance of a section in the direction of the x -axis (kip-in.)
- M_{ry} = uniaxial factored flexural resistance of a section in the direction of the y -axis (kip-in.)
- e_x = eccentricity of the applied factored axial force in the x direction, i.e., $= M_{uy}/P_u$ (in.)
- e_y = eccentricity of the applied factored axial force in the y direction, i.e., $= M_{ux}/P_u$ (in.)

The factored axial resistance P_{rx} and P_{ry} shall not be taken to be greater than the product of the resistance factor, ϕ , and the maximum nominal compressive resistance given by either Eqs. 5.6.4.4-2 or 5.6.4.4-3, as appropriate.

5.6.4.6—Spirals, Hoops, and Ties

The following assumptions may be used for design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi.

For spirals or hoops with closure made using a full-welded splice, a full-mechanical coupler, or by overlapping with hooks around longitudinal bars, the

The procedure for calculating corresponding values of M_{rx} and P_{rx} or M_{ry} and P_{ry} can be found in most texts on reinforced concrete design.

ratio of spiral or hoop reinforcement to total volume of concrete core, ρ_s , shall be determined as:

$$\rho_s = \frac{4A_{sp}}{(d_c s)} \geq 0.45 \left(\frac{A_g}{A_c} - 1 \right) \frac{f'_c}{f_{yh}} \quad (5.6.4.6-1)$$

where:

- A_{sp} = cross-sectional area of spiral or hoop (in.²)
- d_c = core diameter of column measured to the outside of transverse reinforcement (in.)
- s = pitch or vertical spacing of transverse reinforcement (in.)
- A_g = gross area of section (in.²)
- A_c = area of core measured to the outside of the transverse reinforcement (in.²)
- f'_c = compressive strength of concrete for use in design (ksi)
- f_{yh} = specified minimum yield strength of transverse reinforcement (ksi) ≤ 100 ksi for elements and connections specified in Article 5.4.3.3; ≤ 75.0 ksi otherwise

Spiral, hoop, and tie reinforcement shall also conform to the provisions of Articles 5.7, 5.10.4, and 5.11.

5.6.4.7—Hollow Rectangular Compression Members

5.6.4.7.1—Wall Slenderness Ratio

The wall slenderness ratio of a hollow rectangular cross-section shall be taken as:

$$\lambda_w = \frac{X_u}{t} \quad (5.6.4.7.1-1)$$

where:

- λ_w = wall slenderness ratio for hollow columns
- X_u = clear length of the constant thickness portion of a wall between other walls or fillets between walls (in.)
- t = thickness of wall (in.)

Wall slenderness greater than 35 may be used only when the behavior and resistance of the wall is documented by analytic and experimental evidence acceptable to the Owner.

C5.6.4.7.1

The definition of the parameter, X_u , is illustrated in Figure C5.6.4.7.1-1, taken from Taylor et al. (1990).

Figure C5.6.4.7.1-1—Illustration of X_u

The test program in Taylor et al. (1990) was limited to the case of loading under simultaneous axial and uniaxial bending about the weak axis of the section. The results of the study have not been confirmed for the case of biaxial bending. Until such a study is completed, the Designer should investigate the effects of biaxial loading on hollow sections.

5.6.4.7.2—Limitations on the Use of the Rectangular Stress Block Method

5.6.4.7.2a—General

Except as specified in Article 5.6.4.7.2c, the equivalent rectangular stress block method shall not be employed in the design of hollow rectangular compression members with a wall slenderness ratio ≥ 15 .

Where the wall slenderness ratio is less than 15, the rectangular stress block method may be used based on a compressive strain of 0.003.

5.6.4.7.2b—Refined Method for Adjusting Maximum Usable Strain Limit

Where the wall slenderness ratio is 15 or greater, the maximum usable strain at the extreme concrete compression fiber is equal to the lesser of the computed local buckling strain of the widest flange of the cross-section, or 0.003.

The local buckling strain of the widest flange of the cross-section may be computed assuming simply supported boundary conditions on all four edges of the flange. Nonlinear material behavior shall be considered by incorporating the tangent material moduli of the concrete and reinforcement in computations of the local buckling strain.

Discontinuous, nonpost-tensioned reinforcement in segmentally constructed hollow rectangular compression members shall be neglected in computations of member strength.

Flexural resistance shall be calculated using the principles of Article 5.6.3 applied with anticipated stress-strain curves for the types of material to be used.

5.6.4.7.2c—Approximate Method for Adjusting Factored Resistance

The provisions of this article and the rectangular stress block method may be used in lieu of the provisions of Articles 5.6.4.7.2a and 5.6.4.7.2b where the wall slenderness is ≤ 35 .

The factored resistance of a hollow column, determined using a maximum usable strain of 0.003, and the resistance factors specified in Article 5.5.4.2 shall be further multiplied by a factor, ϕ_w , taken as:

- If $\lambda_w \leq 15$, then $\phi_w = 1.0$ (5.6.4.7.2c-1)
- If $15 < \lambda_w \leq 25$, then $\phi_w = 1 - 0.025(\lambda_w - 15)$ (5.6.4.7.2c-2)
- If $25 < \lambda_w \leq 35$, then $\phi_w = 0.75$ (5.6.4.7.2c-3)

5.6.5—Bearing

In the absence of confinement reinforcement in the concrete supporting the bearing device, the factored bearing resistance shall be taken as:

$$P_r = \phi P_n \quad (5.6.5-1)$$

in which:

$$P_n = 0.85 f'_c A_1 m \quad (5.6.5-2)$$

where:

- P_n = nominal bearing resistance (kip)
 A_1 = area under bearing device (in.²)
 m = confinement modification factor

Where the supporting surface is wider than the loaded area on all sides, the modification factor, m , may be determined as follows:

- Where the loaded area is subjected to uniformly distributed bearing stresses:

$$m = \sqrt{\frac{A_2}{A_1}} \leq 2.0 \quad (5.6.5-3)$$

- Where the loaded area is subjected to nonuniformly distributed bearing stresses:

$$m = 0.75 \sqrt{\frac{A_2}{A_1}} \leq 1.50 \quad (5.6.5-4)$$

where:

- A_2 = notional area defined as shown in Figure 5.6.5-1 (in.²)

Otherwise, where the supporting surface is not wider than the loaded area on all sides, m shall be taken as unity.

Figure 5.6.5-1—Determination of Notional Area

Where the supporting surface is sloped or stepped, A_2 may be taken as the area of the lower base of the largest frustum of a right pyramid, cone, or tapered wedge contained wholly within the support and having for its upper base the loaded area, as well as side slopes of 1.0 vertical to 2.0 horizontal as shown in Figure 5.6.5-2.

Figure 5.6.5-2—Determination of A_2 for a Stepped Support

Where the factored applied load exceeds the factored resistance, as specified herein, provisions shall be made to resist the bursting and spalling forces in accordance with Article 5.9.5.6.

5.6.6—Tension Members

5.6.6.1—Resistance to Tension

Members in which the factored loads induce tensile stresses throughout the cross-section shall be regarded as tension members, and the axial force shall be assumed to be resisted only by the steel elements. The provisions of Article 5.10.8.4.4 shall apply.

The factored resistance to uniform tension shall be taken as:

$$P_r = \phi P_n \quad (5.6.6.1-1)$$

where:

ϕ = resistance factor, specified in Article 5.5.4.2
 P_n = nominal resistance of a tie, as specified in Article 5.8.2.4.1

5.6.6.2—Resistance to Combined Tension and Flexure

Members subjected to eccentric tension loading, which induces both tensile and compressive stresses in the cross-section, shall be proportioned in accordance with the provisions of Article 5.6.2.

5.6.7—Control of Cracking by Distribution of Reinforcement

Except for deck slabs designed in accordance with Article 9.7.2, the provisions specified herein shall apply to the reinforcement of all concrete components in which tension in the cross-section exceeds 80 percent of the modulus of rupture, specified in Article 5.4.2.6, at the applicable service limit state load combination specified in Table 3.4.1-1.

The spacing, s , of nonprestressed reinforcement in the layer closest to the tension face shall satisfy the following:

C5.6.7

All reinforced concrete members are subject to cracking under any load condition, including thermal effects and restraint of deformations, which produces tension in the gross section in excess of the cracking strength of the concrete. Locations particularly vulnerable to cracking include those where there is an abrupt change in section and intermediate post-tensioning anchorage zones.

Provisions specified herein are used for the distribution of tension reinforcement to control flexural cracking.

Crack width is inherently subject to wide scatter, even in careful laboratory work, and is influenced by shrinkage and other time-dependent effects. Steps should be taken in detailing of the reinforcement to control cracking. From the standpoint of appearance, many fine cracks are preferable to a few wide cracks. Improved crack control is obtained when the steel reinforcement is well distributed over the zone of maximum concrete tension. Several bars at moderate spacing are more effective in controlling cracking than one or two larger bars of equivalent area.

Extensive laboratory work involving deformed reinforcing bars has confirmed that the crack width at the service limit state is proportional to steel stress. However, the significant variables reflecting steel detailing were found to be the thickness of concrete cover and spacing of the reinforcement.

$$s \leq \frac{700\gamma_e}{\beta_s f_{ss}} - 2d_c \quad (5.6.7-1)$$

in which:

$$\beta_s = 1 + \frac{d_c}{0.7(h - d_c)} \quad (5.6.7-2)$$

where:

- γ_e = exposure factor
 - = 1.00 for Class 1 exposure condition
 - = 0.75 for Class 2 exposure condition
- β_s = ratio of flexural strain at the extreme tension face to the strain at the centroid of the reinforcement layer nearest the tension face
- f_{ss} = calculated tensile stress in nonprestressed reinforcement at the service limit state not to exceed $0.60 f_y$ (ksi)
- d_c = thickness of concrete cover measured from extreme tension fiber to center of the flexural reinforcement located closest thereto (in.)
- h = overall thickness or depth of the component (in.)

Class 1 exposure condition applies when cracks can be tolerated due to reduced concerns of appearance, corrosion, or both. Class 2 exposure condition applies to transverse design of segmental concrete box girders for any loads applied prior to attaining full design concrete compressive strength or when there is increased concern of appearance, corrosion, or both.

When computing the actual stress in the steel reinforcement, axial tension effects shall be considered, while axial compression effects may be considered.

The minimum and maximum spacing of reinforcement shall also comply with the provisions of Articles 5.10.3.1 and 5.10.3.2, respectively.

The effects of bonded prestressing steel may be considered, in which case the value of f_{ss} used in Eq. 5.6.7-1, for the bonded prestressing steel, shall be the stress that develops beyond the decompression state calculated on the basis of a cracked section or strain compatibility analysis.

Eq. 5.6.7-1 is expected to provide a distribution of reinforcement that will control flexural cracking. The equation is based on a physical crack model (Frosch, 2001) rather than the statistically-based model used in previous editions of the specifications. It is written in a form emphasizing reinforcement details, i.e., limiting bar spacing, rather than crack width. Furthermore, the physical crack model has been shown to provide a more realistic estimate of crack widths for larger concrete covers compared to the previous equation (Destefano et al., 2003).

Eq. 5.6.7-1 with Class 1 exposure condition is based on an assumed crack width of 0.017 in. Previous research indicates that there appears to be little or no correlation between crack width and corrosion, however, the different classes of exposure conditions have been so defined in order to provide flexibility in the application of these provisions to meet the needs of the Owner. Class 1 exposure condition could be thought of as an upper bound in regards to crack width for appearance and corrosion. Areas that the Owner may consider for Class 2 exposure condition would include decks and substructures exposed to water. The crack width is directly proportional to the γ_e exposure factor, therefore, if the individual Owner desires an alternate crack width, the γ_e factor can be adjusted directly. For example, a γ_e factor of 0.5 will result in an approximate crack width of 0.0085 in.

Where members are exposed to aggressive exposure or corrosive environments, additional protection beyond that provided by satisfying Eq. 5.6.7-1 may be provided by decreasing the permeability of the concrete, waterproofing the exposed surface, or both.

Cracks in segmental concrete box girders may result from stresses due to handling and storing segments for precast construction and to stripping forms and supports from cast-in-place construction before attainment of the nominal f'_c .

The β_s factor, which is a geometric relationship between the crack width at the tension face versus the crack width at the reinforcement level, has been incorporated into the basic crack control equation in order to provide uniformity of application for flexural member depths ranging from thin slabs in box culverts to deep pier caps and thick footings. The theoretical definition of β_s may be used in lieu of the approximate expression provided.

Research by Shahrooz et al. (2011) indicates that Eq. 5.6.7-1 can be applied to reinforcement with specified minimum yield strengths up to 100 ksi but the tensile stress in the steel reinforcement at the service limit state, f_{ss} , cannot exceed 60.0 ksi with $f_y = 100$ ksi. A limit of $f_{ss} \leq 0.60 f_y$ was adopted.

In certain situations involving higher-strength reinforcement or large concrete cover, the use of Eq. 5.6.7-1 can result in small or negative values for s . Where higher strength reinforcement is used, an analysis of five crack-control equations suggests a bar spacing not less than 5.0 in. for control of flexural cracking.

Unless justified by successful past practice, the actual concrete cover thickness should be used in the computation of d_c .

Where flanges of reinforced concrete T-girders and box girders are in tension at the service limit state, the flexural tension reinforcement shall be distributed over the lesser of the following:

- The effective flange width, specified in Article 4.6.2.6,
- A width equal to one tenth of the average of adjacent spans between bearings.

If the effective flange width exceeds one tenth the span, additional longitudinal reinforcement, with area not less than 0.4 percent of the excess slab area, shall be provided in the outer portions of the flange.

If d_t of nonprestressed members exceeds 3.0 ft, longitudinal skin reinforcement shall be uniformly distributed along both side faces of the component for a distance $d_t/2$ nearest the flexural tension reinforcement. The area of skin reinforcement, A_{sk} , in in.²/ft of height on each side face shall satisfy:

$$A_{sk} \geq 0.012 (d_t - 30) \quad (5.6.7-3)$$

where:

d_t = distance from the extreme compression fiber to the centroid of extreme tension steel element (in.)

However, the total area of longitudinal skin reinforcement (per face) need not exceed one-fourth of the required flexural tensile reinforcement.

The maximum spacing of the skin reinforcement shall not exceed the lesser of:

- $d_t/6$;
- 12.0 in.

Such reinforcement may be included in strength computations if a strain compatibility analysis is made to determine stresses in the individual bars or wires.

5.7—DESIGN FOR SHEAR AND TORSION—B-REGIONS

5.7.1—Design Procedures

5.7.1.1—Flexural Regions

Where it is reasonable to assume that plane sections remain plane after loading, regions of components may be designed for shear and torsion using either the

Where large concrete cover is used, past successful practice suggests a value of d_c not greater than 2.0 in. plus the bar radius for calculation purposes. The limit of 2.0 in. plus the bar radius is the limit that was used in these Specifications prior to the introduction of the current version of Eq. 5.6.7-1 in 2005.

Distribution of the negative reinforcement for control of cracking in T-girders should be made in the context of the following considerations:

- Wide spacing of the reinforcement across the full effective width of flange may cause some wide cracks to form in the slab near the web.
- Close spacing near the web leaves the outer regions of the flange unprotected.

The one-tenth of the span limitation is to guard against an excessive spacing of bars, with additional reinforcement required to protect the outer portions of the flange.

The requirements for skin reinforcement are based on work reported in Frantz and Breen (1978). For beams with a depth, d_t , greater than 3.0 ft, some reinforcement should be placed near the vertical faces in the tension zone to control cracking in the web. Without such auxiliary steel, the width of the cracks in the web may greatly exceed the crack widths at the level of the flexural tension reinforcement.

C5.7.1.1

The sectional model is appropriate for the design of typical bridge girders, slabs, and other regions of components where the assumptions of traditional

sectional model as specified in Article 5.7.3 or the STM as specified in Article 5.8.2. The requirements of Article 5.7.2 shall apply.

In lieu of the provisions of Article 5.7.3, segmental post-tensioned concrete box girder bridges may be designed for shear and torsion using the provisions of Article 5.12.5.3.8.

Components in which the distance from the point of zero shear to the face of the support is less than $2d$, or components in which a load causing more than one half (one third in case of segmental box girders) of the shear at a support is closer than $2d$ from the face of the support, may be considered to be deep components for which the provisions of Article 5.8.2 apply.

5.7.1.2—Regions near Discontinuities

Regions of members where the plane sections assumption of flexural theory is not valid should be considered to be D-Regions and should be designed for shear and torsion using the STM, as specified in Article 5.8.2, or the legacy methods of Article 5.8.4.

5.7.1.3—Interface Regions

Interfaces between elements shall be designed for shear transfer in accordance with the provisions of Article 5.7.4.

5.7.1.4—Slabs and Footings

Slab-type regions shall be designed for shear in accordance with the provisions of Article 5.7.3 or Article 5.12.8.6.

5.7.1.5—Webs of Curved Post-Tensioned Box Girder Bridges

Curved post-tensioned box girders having an overall clear height, h_c , in excess of 4.0 ft shall be designed for all of the following combined effects, considering all appropriate losses:

- The combined effects of global shear resulting from vertical shear and torsion,
- Transverse web regional bending resulting from lateral prestress force, and
- Transverse web bending from vertical loads and transverse post-tensioning.

The applicable provisions of Articles 5.9.5.4.3 and 5.9.5.4.4 shall also be considered.

engineering beam theory are valid. This traditional approach applies even to the ends of typical beams provided that the provisions of Article 5.7.3.5 are satisfied and conventional detailing practices are followed. This theory assumes that the response at a particular section depends only on the calculated values of the sectional force effects, i.e., moment, shear, axial load, and torsion, and does not consider the specific details of how the force effects were introduced into the member. Although the STM can be applied to flexural regions, it is more appropriate for regions near discontinuities where the actual flow of forces should be considered in more detail.

C5.7.1.2

The response of regions adjacent to abrupt changes in cross-section, openings, dapped ends, diaphragms, deep beams, and corbels is influenced significantly by the details of how the loads are introduced into the region and how the region is supported.

C5.7.1.5

Transverse web bending is a function of the vertical loads, restoring effect of the longitudinal prestressing, the Resal effect, and any transverse prestressing. Considering global web shear and regional web transverse bending alone will tend to underestimate the amount of vertical reinforcement required in the webs. More rigorous approaches that consider the interaction of these combined forces are presented in Menn (1990) and Nutt et al. (2008).

5.7.2—General Requirements

5.7.2.1—General

Except where principal tensile stresses are investigated under the provisions of Article 5.9.2.3.3, design for shear and torsion shall be performed at the strength or extreme event limit state load combinations as specified in Article 3.4.1.

The secondary shear effects from prestressing shall be included in the *PS* load, defined in Article 3.3.2.

In lieu of a more refined analysis, the torsional loading from a slab may be assumed as linearly distributed along the member.

The effects of axial tension due to creep, shrinkage, and thermal effects in restrained members shall be considered wherever applicable.

The vertical component of inclined tendons or strands shall only be considered to reduce the applied shear on the webs for tendons which extend through the web depth, engage both the flexural compression and flexural tension zones, and are fully developed or anchored by one of the following:

- anchorages,
- deviators, or
- internal ducts located in the top or bottom one third of the webs.

The component of inclined flexural compression or tension, in the direction of the applied shear, in variable depth members shall be considered when determining the factored shear force where its effect is detrimental (increase in shear load) but may be considered if its effect is beneficial (decrease in shear load).

The values of the compressive strength of concrete for use in design shall not exceed 15.0 ksi for shear using the provisions of Article 5.7.3 or 10.0 ksi for torsion or for torsion and shear.

The factored shear resistance, V_r , shall be taken as:

$$V_r = \phi V_n \quad (5.7.2.1-1)$$

The factored torsional resistance, T_r , shall be taken as:

$$T_r = \phi T_n \quad (5.7.2.1-2)$$

where:

- ϕ = resistance factor, as specified in Article 5.5.4.2
 V_n = nominal shear resistance, specified in Article 5.7.3.3 (kip)
 T_n = nominal torsional resistance, specified in Article 5.7.3.6 (kip-in.)

C5.7.2.1

See Appendix C5 for limits of the maximum design concrete compressive strength applicable to affected articles. An exception to the listed assumptions is the use of the Plastic Stress Distribution Method (PSDM) for composite concrete filled steel tubes, which is addressed in Section 6.

Torsion is often designated as either compatibility torsion or equilibrium torsion as illustrated in Figure C5.7.2.1-1. Equilibrium torsion is required for stable equilibrium by the topology of the structure and must be addressed in the design. All torsion in a statically determinant structure is equilibrium torsion. Torsion in a statically indeterminate structure may be either compatibility or equilibrium torsion. Torsion which results from rotational restraint but which is not required to keep the applied loads in stable equilibrium because other load paths exist to support the loads is called compatibility torsion. It is not necessary to design for compatibility torsion as long as the other load paths are properly designed for the redistributed forces. Consideration should be given to the aesthetic issues that may be caused by cracking that could be associated with not designing for compatibility torsion.

In a statically indeterminate structure where significant reduction of torsional moment in a member can occur due to redistribution of internal forces upon cracking, the applied factored torsional moment at a section, T_u , may be reduced to ϕT_{cr} , provided that moments and forces in the member and in adjoining members are adjusted to account for the redistribution.

Figure C5.7.2.1-1 Equilibrium and Compatibility Torsion (Rameriz and Breen, 1983)

Sections that are designed for live loads using approximate methods of analysis in Article 4.6.2.2 need not be investigated for torsion.

If the factored torsional moment is less than the indicated fraction of the factored pure torsional cracking moment, it will cause only a very small reduction in shear capacity or flexural capacity and, hence, can be neglected.

Torsional effects shall be investigated where:

$$T_u > 0.25\phi T_{cr} \quad (5.7.2.1-3)$$

- For solid shapes:

$$T_{cr} = 0.126K\lambda\sqrt{f'_c} \frac{A_{cp}^2}{p_c} \quad (5.7.2.1-4)$$

- For hollow shapes:

$$T_{cr} = 0.126K\lambda\sqrt{f'_c} 2A_o b_e \quad (5.7.2.1-5)$$

in which:

$$K = \sqrt{1 + \frac{f_{pc}}{0.126\lambda\sqrt{f'_c}}} \leq 2.0 \quad (5.7.2.1-6)$$

where:

- T_u = applied factored torsional moment (kip-in.)
- ϕ = resistance factor, specified in Article 5.5.4.2
- T_{cr} = torsional cracking moment (kip-in.)
- λ = concrete density modification factor, as specified in Article 5.4.2.8
- f'_c = compressive strength of concrete for use in design (ksi)
- A_{cp} = area enclosed by outside perimeter of concrete cross-section (in.²)
- p_c = length of outside perimeter of the concrete section (in.)
- A_o = area enclosed by the shear flow path, including any area of holes therein (in.²)
- b_e = effective width of the shear flow path taken as the minimum thickness of the exterior webs or flanges comprising the closed box section (in.).

For hollow shapes of typical proportions, A_o can be taken as the area enclosed by the centerlines of the exterior webs and flanges that form the closed section.

See Article C5.9.2.3.3 for additional discussion of shear flow in hollow shapes.

b_e shall be adjusted to account for the presence of ducts.

f_{pc} = unfactored compressive stress in concrete after prestress losses have occurred either at the centroid of the cross-section resisting transient loads or at the junction of the web and flange where the centroid lies in the flange (ksi)

The value of b_e , defined above, shall not exceed A_{cp}/p_c unless a more refined analysis is utilized to determine a larger value.

The effects of any openings or ducts in members shall be considered. K shall not be taken greater than 1.0 for any section where the stress in the extreme tension fiber, calculated on the basis of gross section properties, due to factored load and effective prestress force exceed $0.19 \lambda \sqrt{f'_c}$ in tension.

When calculating K for a section subject to factored axial force, N_u , f_{pc} shall be replaced with $f_{pc} - N_u/A_g$. N_u shall be taken as a positive value when the axial force is tensile and as a negative value when it is compressive.

5.7.2.2—Transfer and Development Lengths

The provisions of Article 5.9.4.3 shall be considered for longitudinal reinforcement resisting tension caused by shear.

5.7.2.3—Regions Requiring Transverse Reinforcement

Except for footings, culverts, slabs, and other members that meet the Article 5.2 definition of a slab, transverse reinforcement shall be provided where:

- $V_u > 0.5\phi(V_c + V_p)$ (5.7.2.3-1)

or

- Where consideration of torsion is required by Eq. 5.7.2.1-3.

where:

V_u = factored shear force (kip)
 ϕ = resistance factor, specified in Article 5.5.4.2
 V_c = nominal shear resistance of the concrete (kip)
 V_p = component of prestressing force in the direction of the shear force

An example of a more refined analysis would be a plate model of the cross-section subjected to a torsional load.

The current recommendation for determining the effective web or flange thickness, b_e , is that the diameters of corrugated metal or plastic ungrouted ducts or one half the diameters of grouted ducts be subtracted from the web or flange thickness at the location of these ducts (AASHTO, 1999). For determining the shear capacity of girders containing grouted ducts in the web, no reduction in effective web or flange thickness is required provided the λ_{duct} factor of Article 5.7.3.3 is employed in calculating V_s . This approach is consistent with the fundamentals of Modified Compression Field Theory (MCFT) (Vecchio and Collins, 1986), which is rooted in the ability of cracked concrete to transfer shear.

C5.7.2.2

The reduced prestress in the transfer length reduces V_p , f_{pc} , and f_{pe} . The transfer length influences the tensile force that can be resisted by the tendons at the inside edge of the bearing area, as described in Article 5.7.3.5.

C5.7.2.3

Transverse reinforcement is required in all regions where there is a significant chance of diagonal cracking. Slabs are defined as members that have widths at least four times their effective depth, and therefore members such as cantilever semi-gravity (conventional) retaining walls can be considered exempt from these requirements.

5.7.2.4—Types of Transverse Reinforcement

Transverse reinforcement to resist shear may consist of:

- Stirrups perpendicular to the longitudinal axis of the member;
- Welded wire reinforcement, with wires located perpendicular to the longitudinal axis of the member, provided that the transverse wires are certified to undergo a minimum elongation of four percent, measured over a gauge length of at least 4.0 in. including at least one cross wire;
- Anchored prestressed tendons, detailed and constructed to minimize seating and time-dependent losses, which make an angle not less than 45 degrees with the longitudinal tension reinforcement;
- Combinations of stirrups, tendons, and bent longitudinal bars;
- Spirals, hoops, or ties and cross-ties;
- Inclined stirrups making an angle of not less than 45 degrees with the longitudinal tension reinforcement; or
- Bent longitudinal bars in nonprestressed members with the bent portion making an angle of 30 degrees or more with the longitudinal tension reinforcement.

Inclined stirrups and bent longitudinal reinforcement shall be spaced so that every 45-degree line, extending towards the reaction from mid-depth of the member, $h/2$, to the longitudinal tension reinforcement shall be crossed by at least one line of transverse reinforcement.

Transverse reinforcement shall be detailed such that the shear force between different elements or zones of a member are effectively transferred.

Torsional reinforcement shall consist of both transverse and longitudinal reinforcement. Longitudinal reinforcement shall consist of bars and/or tendons. Transverse reinforcement may consist of:

- Closed stirrups perpendicular to the longitudinal axis of the member, as specified in Article 5.10.8.2.6d;
- A closed cage of welded wire reinforcement with transverse wires perpendicular to the longitudinal axis of the member; or
- Ties or hoops.

5.7.2.5—Minimum Transverse Reinforcement

Where transverse reinforcement is required as specified in either Article 5.7.2.3 or Article 5.12.5.3.8c, and nonprestressed reinforcement is used to satisfy that requirement, the area of steel shall satisfy:

$$A_v \geq 0.0316 \lambda \sqrt{f'_c} \frac{b_v s}{f_y} \quad (5.7.2.5-1)$$

C5.7.2.4

Stirrups inclined at less than 45 degrees to the longitudinal reinforcement are difficult to anchor effectively against slip and, hence, are not permitted. Inclined stirrups and prestressed tendons should be oriented to intercept potential diagonal cracks at an angle as close to normal as practical.

To increase shear capacity, transverse reinforcement should be capable of undergoing substantial strain prior to failure. Welded wire reinforcement, particularly if fabricated from small wires and not stress-relieved after fabrication, may fail before the required strain is reached. Such failures may occur at or between the cross-wire intersections.

For some large bridge girders, prestressed tendons perpendicular to the member axis may be an efficient form of transverse reinforcement. Care must be taken to avoid excessive loss of prestress due to anchorage slip or seating losses because the tendons are short. The requirements for transverse reinforcement assume it is perpendicular to the longitudinal axis of prismatic members or vertical for nonprismatic or tapered members. Requirements for bent bars were added to make the provisions consistent with those in AASHTO (2002).

C5.7.2.5

A minimum amount of transverse reinforcement is required to restrain the growth of diagonal cracking and to increase the ductility of the section. A larger amount of transverse reinforcement is required to control cracking as the concrete strength is increased.

Additional transverse reinforcement may be required for transverse web bending.

where:

- A_v = area of transverse reinforcement within distance s (in.²)
 λ = concrete density modification factor, as specified in Article 5.4.2.8
 b_v = width of web adjusted for the presence of ducts, as specified in Article 5.7.2.8 (in.)
 s = spacing of transverse reinforcement (in.)
 f_y = yield strength of transverse reinforcement (ksi) ≤ 100 ksi

The design yield strength of prestressed transverse reinforcement in Eq. 5.7.2.5-1 shall be taken as the effective stress, after allowance for all prestress losses, plus 60.0 ksi, but not greater than f_{py} .

For segmental post-tensioned concrete box girder bridges where transverse reinforcement is not required by Article 5.12.5.3.8c, the minimum area of transverse shear reinforcement per web shall not be less than the equivalent of two #4 Grade 60 reinforcement bars per foot of length.

5.7.2.6—Maximum Spacing of Transverse Reinforcement

The spacing of the transverse reinforcement shall not exceed the maximum permitted spacing, s_{max} , determined as:

- If $v_u < 0.125 f'_c$, then:

$$s_{max} = 0.8d_v \leq 24.0 \text{ in.} \quad (5.7.2.6-1)$$
- If $v_u \geq 0.125 f'_c$, then:

$$s_{max} = 0.4d_v \leq 12.0 \text{ in.} \quad (5.7.2.6-2)$$

where:

- v_u = shear stress, calculated in accordance with Article 5.7.2.8 (ksi)
 d_v = effective shear depth, as defined in Article 5.7.2.8 (in.)

For segmental post-tensioned concrete box girder bridges, spacing of closed stirrups or closed ties required to resist shear effects due to torsional moments shall not exceed one-half of the shortest dimension of the cross-section, nor 12.0 in.

Testing by Shahrooz et al. (2011) has verified these minimum values of transverse reinforcement for reinforcing steel with specified minimum yield strengths up to 100 ksi for both prestressed and nonprestressed members subjected to flexural shear without torsion for applications in Seismic Zone 1. See Article C5.4.3.3 for additional information.

Prior to the seventh edition (2014), these Specifications had a minimum transverse reinforcement requirement for segmentally constructed, post-tensioned concrete box girders that was not a function of concrete strength. Observations in shear testing of prestressed concrete girders indicate that higher strength concrete with lightly reinforced girders can fail soon after cracking. Since the limit for segmental structures was both less conservative and not tied to concrete strength, it was eliminated.

C5.7.2.6

NCHRP Report 579 (Hawkins and Kuchma, 2007) indicates that in prestressed girders the angle of diagonal cracking can be sufficiently steep that a transverse bar reinforcement spacing of $0.8d_v$ could result in no stirrups intersecting and impeding the opening of a diagonal crack. A limit of $0.6d_v$ may be appropriate in some situations. Reducing the transverse bar reinforcement diameter is another approach taken by some.

These spacing requirements were verified by Shahrooz et al. (2011) for transverse reinforcement with specified minimum yield strengths up to 100 ksi for prestressed and nonprestressed members subjected to flexural shear without torsion for applications in Seismic Zone 1. See Article C5.4.3.3 for additional information.

5.7.2.7—Design and Detailing Requirements

Transverse reinforcement shall be anchored at both ends in accordance with the provisions of Article 5.10.8.2.6. For composite flexural members, extension of beam shear reinforcement into the deck slab may be considered when determining if the development and anchorage provisions of Article 5.10.8.2.6 are satisfied.

For elements and connections specified in Article 5.4.3.3 subjected to flexural shear without torsion, the design yield strength of nonprestressed transverse reinforcement shall be taken as the specified minimum yield strength, but not to exceed 100 ksi. For all other elements and connections, the design yield strength of nonprestressed transverse reinforcement shall be taken equal to the specified yield strength where the latter does not exceed 60.0 ksi. For nonprestressed transverse reinforcement with yield strength in excess of 60.0 ksi, the design yield strength shall be taken as the stress corresponding to a strain of 0.0035, but not to exceed 75.0 ksi.

Where welded wire reinforcement is used as transverse reinforcement, it shall be anchored at both ends in accordance with Article 5.10.8.2.6c. No welded joints other than those required for anchorage shall be permitted.

5.7.2.8—Shear Stress on Concrete

The shear stress on the concrete shall be determined as:

$$v_u = \frac{|V_u - \phi V_p|}{\phi b_v d_v} \quad (5.7.2.8-1)$$

where:

ϕ = resistance factor for shear, specified in Article 5.5.4.2

b_v = effective web width taken as the minimum web width, measured parallel to the neutral axis, between the resultants of the tensile and compressive forces due to flexure, or for circular sections, the diameter of the section,

C5.7.2.7

To be effective, the transverse reinforcement should be anchored at each end in a manner that minimizes slip. Fatigue of welded wire reinforcement is not a concern in prestressed members as long as the specially fabricated reinforcement is detailed to have welded joints only in the flanges where shear stress is low.

Some of the provisions of Article 5.7.3 are based on the assumption that the strain in the transverse reinforcement has to attain a value of 0.002 to develop its yield strength. For prestressed tendons, it is the additional strain required to increase the stress above the effective stress caused by the prestress that is of concern. Previous versions limited the design yield strength of nonprestressed transverse reinforcement to 75.0 ksi or a stress corresponding to a strain of 0.0035 to provide control of crack widths at service limit state. Shahrooz et al. (2011) compare the performance of transverse reinforcement with specified yield strengths of 60.0 and 100 ksi in prestressed and nonprestressed members subjected to flexural shear only, under Seismic Zone 1 conditions. The results do not show any discernable difference between the performance of the two types of transverse reinforcement at either service or strength limit states. Griezic (1994), Ma et al. (2000), and Bruce (2003) indicate that the performance of higher-strength steels as shear reinforcement has been satisfactory. Use of relatively small diameter deformed welded wire reinforcement at relatively small spacing, compared to individually field tied reinforcing bars, results in improved quality control and improved member performance in service.

The components in the direction of the applied shear of inclined flexural compression and inclined flexural tension can be accounted for in the same manner as the component of the longitudinal prestressing force, V_p .

C5.7.2.8

Figure C5.7.2.8-1—Illustration of the Terms b_v and d_v

For flexural members, the distance between the resultants of the tensile and compressive forces due to flexure can be determined as:

modified for the presence of ducts where applicable (in.) For grouted ducts, no modification is necessary. For ungrouted ducts, reduce b_v by the diameter of the duct.

d_v = effective shear depth taken as the distance, measured perpendicular to the neutral axis, between the resultants of the tensile and compressive forces due to flexure; it need not be taken to be less than the greater of $0.9d_e$ or $0.72h$ (in.)

in which:

$$d_e = \frac{A_{ps}f_{ps}d_p + A_s f_y d_s}{A_{ps}f_{ps} + A_s f_y} \quad (5.7.2.8-2)$$

The provisions of Article 5.7.2.1 regarding deductions for post-tensioning ducts shall apply.

$$d_v = \frac{M_n}{A_s f_y + A_{ps} f_{ps}} \quad (C5.7.2.8-1)$$

For girders with debonded strands, d_v is calculated by neglecting the area of debonded strands for the length over which strands are debonded. For regions where debonded strands are bonded for distances less than ℓ_d , the value of d_v is calculated accounting for the lack of full development of the strand according to Article 5.9.4.3.2. Determine ℓ_d using Eq. 5.9.4.3.2-1 with the value of κ taken as 2.0.

For girders designed as individual I-girders, or as individual web lines, b_v is taken as the minimum width of the single web of the girder being considered. For box girders designed as a single unified section, b_v is taken as the total minimum width of all the webs in the cross-section.

In continuous members near the point of inflection, if Eq. C5.7.2.8-1 is used, it should be evaluated in terms of both the top and the bottom reinforcement. Note that other limitations on the value of d_v to be used are specified and that d_v is the value at the section at which shear is being investigated.

The AASHTO Standard Specifications permitted d for prestressed members to be taken as $0.8h$. The $0.72h$ limit on d_v is $0.9 \times 0.8h$.

Post-tensioning ducts act as discontinuities and, hence, can reduce the crushing strength of concrete webs. In determining which level over the effective depth of the beam has the minimum width, and hence controls b_v , levels which contain a post-tensioning duct or several ducts shall have their widths reduced. Thus, for the section shown in Figure C5.7.2.8-1, the post-tensioning duct in the position shown would not reduce b_v , because it is not at a level where the width of the section is close to the minimum value. If the location of the tendon were raised such that the tendon is located within the narrow portion of the web, the value of b_v would be reduced.

For circular members, such as reinforced concrete columns or prestressed concrete piles, d_v can be determined from Eq. C5.7.2.8-1 provided that M_n is calculated ignoring the effects of axial load and that the reinforcement areas, A_s and A_{ps} , are taken as the reinforcement in one half of the section. Alternatively, d_v can be taken as $0.9d_e$, where:

$$d_e = \frac{D}{2} + \frac{D_r}{\pi} \quad (C5.7.2.8-2)$$

where:

D = external diameter of the circular member (in.)

D_r = diameter of the circle passing through the centers of the longitudinal reinforcement (in.)

Figure C5.7.2.8-2—Illustration of Terms b_v , d_v , and d_e for Circular Sections

Circular members usually have the longitudinal reinforcement uniformly distributed around the perimeter of the section. When the member cracks, the highest shear stresses typically occur near the mid-depth of the section. This is also true when the section is not cracked. It is for this reason that the effective web width can be taken as the diameter of the section.

5.7.3—Sectional Design Model

5.7.3.1—General

The sectional design model may be used for shear design where permitted in accordance with the provisions of Article 5.7.1. The provisions herein may be used for design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi.

In lieu of the methods specified herein, the resistance of members in shear or in shear combined with torsion may be determined by satisfying the conditions of equilibrium and compatibility of strains and by using experimentally verified stress-strain relationships for reinforcement and for diagonally cracked concrete. Where consideration of simultaneous shear in a second direction is warranted, investigation shall be based either on the principles outlined above or on a three-dimensional strut-and-tie model.

5.7.3.2—Sections Near Supports

In the absence of a concentrated load within d_v , and where the reaction force in the direction of the applied shear introduces compression into the end region of a member, the location of the critical section for shear

C5.7.3.1

In the sectional design approach, the component is investigated by comparing the factored shear force and the factored shear resistance at a number of sections along its length. Usually this check is made at the tenth points of the span and at locations near the supports.

The extension of these shear provisions to normal weight concretes with compressive strengths up to 15.0 ksi is based on the work presented in NCHRP Report 579 (Hawkins and Kuchma, 2007) (Kuchma et al., 2008).

See Articles 5.11.3 and 5.11.4.1.3 for additional requirements for Seismic Zones 2, 3, and 4, and Articles 5.7.1.2 and 5.7.3.2 for additional requirements for member end regions.

An appropriate nonlinear finite element analysis or a detailed sectional analysis would satisfy the requirements of this article. More information on appropriate procedures and a computer program that satisfies these requirements are given by Collins and Mitchell (1991). One possible approach to the analysis of biaxial shear and other complex loadings on concrete members is outlined in Rabbat and Collins (1978), and a corresponding computer-aided solution is presented in Rabbat and Collins (1976). A discussion of the effect of biaxial shear on the design of reinforced concrete beam-to-column joints can be found in Paulay and Priestley (1992).

C5.7.3.2

Loads close to the support are transferred directly to the support by compressive arching action without causing additional stresses in the stirrups (see Figure C5.7.3.2, Part a). Loads away from supports

shall be taken as d_v from the face of the support and the shear reinforcement required at the critical section shall be extended to the support. The uniform loads and self-weight of the member in the immediate vicinity of the support directly get transferred into the support and do not impose an additional demand on stirrups located within d_v of the support.

Where there is a concentrated load within d_v or the reaction force in the direction of the applied shear introduces tension into the end region of a member the shear load and shear resistance shall be taken at the face of the support. Where the beam-type element extends on both sides of the reaction area, the design section on each side of the reaction shall be determined separately based upon the loads on each side of the reaction and whether their respective contribution to the total reaction introduces tension or compression into the end region.

For post-tensioned beams, anchorage zone reinforcement shall be provided as specified in Article 5.9.5.6. For pretensioned beams, a reinforcement cage confining the ends of strands shall be provided as specified in Article 5.9.4.4. For nonprestressed beams supported on bearings that introduce compression into the member, only minimal transverse reinforcement may be provided between the inside edge of the bearing plate or pad and the end of the beam.

create a compression field and vertical component of the forces generated in the compression field introduce a demand on stirrups (see Figure C5.7.3.2, Part b). Bircher et al. (2009) shows that practically all of the concentrated load positioned within a distance, d , away from the support gets transferred directly into the support. Both loads near supports and away from supports introduce stresses in the CCT node (see Article 5.8.2.2 for definition) that forms above the supports, and those stresses should be checked in accordance with the requirements of Article 5.8.2. Alternatively, the complex state of stress that results from the presence of a concentrated force near a support may be accounted for using sectional design models by making conservative assumptions for shear design. In the context of sectional design, calculating capacity and demand at the face of the support conservatively takes into account the complex state of stress that results from the load introduction into the member near a support.

a. Direct Load Transfer into a Support ($a \leq d$)

b. Indirect Load Transfer into a Support ($a > d$)

Figure C5.7.3.2-1—Load Transfer into a Support

If the shear stress at the design section calculated in accordance with Article 5.7.2.8 exceeds $0.18f'_c$ and the beam-type element is not built integrally with the support, its end region shall be designed using the STM specified in Article 5.8.2.

Where a beam is loaded on top and its end is not built integrally into the support, all the shear funnels down into the end bearing. Where the beam has a thin web so that the shear stress in the beam exceeds $0.18f'_c$, there is the possibility of a local diagonal compression or horizontal shear failure along the interface between the web and the lower flange of the beam. Usually the inclusion of additional transverse reinforcement cannot prevent this type of failure and either the section size must be increased or the end of the beam designed using an STM.

5.7.3.3—Nominal Shear Resistance

The nominal shear resistance, V_n , shall be determined as the lesser of both of the following:

C5.7.3.3

As noted in Article 5.7.2.3 for members subjected to flexural shear without torsion, transverse

$$V_n = V_c + V_s + V_p \quad (5.7.3.3-1)$$

$$V_n = 0.25 f'_c b_v d_v + V_p \quad (5.7.3.3-2)$$

in which:

$$V_c = 0.0316 \beta \lambda \sqrt{f'_c} b_v d_v \quad (5.7.3.3-3)$$

$$V_s = \frac{A_v f_y d_v (\cot \theta + \cot \alpha) \sin \alpha}{s} \lambda_{duct} \quad (5.7.3.3-4)$$

$$\lambda_{duct} = 1 - \delta \left(\frac{\phi_{duct}}{b_w} \right)^2 \quad (5.7.3.3-5)$$

where:

- V_p = component of prestressing force in the direction of the shear force; positive if resisting the applied shear
- b_v = effective web width taken as the minimum web width within the depth d_v , as determined in Article 5.7.2.8 (in.)
- d_v = effective shear depth, as determined in Article 5.7.2.8 (in.)
- β = factor indicating ability of diagonally cracked concrete to transmit tension and shear, as specified in Article 5.7.3.4
- λ = concrete density modification factor, as specified in Article 5.4.2.8
- A_v = area of transverse reinforcement within a distance, s (in.²)
- θ = angle of inclination of diagonal compressive stresses, as determined in Article 5.7.3.4 (degrees)
- α = angle of inclination of transverse reinforcement to longitudinal axis (degrees)
- s = spacing of transverse reinforcement measured in a direction parallel to the longitudinal reinforcement (in.)
- λ_{duct} = shear strength reduction factor accounting for the reduction in the shear resistance provided by transverse reinforcement due to the presence of a grouted post-tensioning duct. Taken as 1.0 for ungrouted post-tensioning ducts and with a reduced web or flange width to account for the presence of ungrouted duct.
- δ = duct diameter correction factor, taken as 2.0 for grouted ducts
- ϕ_{duct} = diameter of post-tensioning duct present in the girder web within depth d_v (in.)
- b_w = gross width of web, not reduced for the presence of post-tensioning ducts (in.)

Where transverse reinforcement consists of a single longitudinal bar or a single group of parallel longitudinal bars bent up at the same distance from the support, the shear resistance V_s provided by these bars shall be determined as:

reinforcement with specified minimum yield strengths up to 100 ksi is permitted for elements and connections specified in Article 5.4.3.3.

The limit in Article 5.7.3.3 was derived from the MCFT (Vecchio and Collins, 1986) and has been validated by numerous experiments on prestressed and nonprestressed concrete members (Saleh and Tadros, 1997) (Lee et al., 2010).

The upper limit of V_n , given by Eq. 5.7.3.3-2, is intended to ensure that the concrete in the web of the beam will not crush prior to yield of the transverse reinforcement.

Where $\alpha = 90$ degrees, Eq. 5.7.3.3-4 reduces to:

$$V_s = \frac{A_v f_y d_v \cot \theta}{s} \lambda_{duct} \quad (C5.7.3.3-1)$$

For girders designed as individual girders, or as individual webs lines, A_v is taken as the reinforcing in the single web of the girder being considered. For box girders designed as a single unified section, A_v is taken as the total reinforcing in all the webs in the cross-section.

The angle θ is also taken as the angle between a strut and the longitudinal axis of a member.

The traditional approach to proportioning transverse reinforcement involves the determination of the required stirrup spacing at discrete sections along the member. The stirrups are then detailed such that this spacing is not exceeded over a length of the beam extending from the design section to the next design section out into the span. In such an approach, the shear demand and resistance provided is as shown in Figure C5.7.3.3-1.

In situations where a significant amount of the load is applied below the mid-depth of the member, such as inverted T-beam pier caps, and the section model is used to design for shear, it is more appropriate to use the traditional approach to the design of transverse reinforcement shown in Figure C5.7.3.3-1.

Figure C5.7.3.3-1—Traditional Shear Design

$$V_s = A_v f_y (\sin \alpha) \lambda_{duct} \leq 0.095 \lambda \sqrt{f'_c} b_v d_v \quad (5.7.3.3-6)$$

Where bent longitudinal reinforcement is used, only the center three fourths of the inclined portion of the bent bar shall be considered effective for transverse reinforcement.

Where more than one type of transverse reinforcement is used to provide shear resistance in the same portion of a member, the shear resistance, V_s , shall be determined as the sum of V_s values computed from each type.

For typical cases where the applied load acts at or above the mid-depth of the member, it is practical to take the traditional approach as shown in Figure C5.7.3.3-1 or a more liberal yet conservative approach as shown in Figure C5.7.3.3-2 which has the effect of extending the required stirrup spacing for a distance of $0.5d_v \cot \theta$ toward the bearing.

Figure C5.7.3.3-2—Simplified Design Section for Loads Applied at or above the Mid-Depth of the Member

Requirements for bent bars were added to make the provisions consistent with those in AASHTO (2002).

The shear strength reduction factor λ_{duct} is based on research that conducted and examined full-scale tests of post-tensioned concrete girder bridges. Moore et al. (2015) examine both plastic and metal grouted ducts used in spliced girders. If the λ_{duct} factor is used in determining the shear capacity of post-tensioned girders containing ducts in the web, no reduction in effective web thickness is required (i.e. $b_e = b_w$). For elements with ungrouted ducts, λ_{duct} factor must be taken as 1.0 and b_v must be reduced to account for the duct diameter. This is consistent with methods used in past editions of the AASHTO LRFD Bridge Design Specifications (Moore et al., 2015).

While Moore et al. (2015) and Williams et al. (2015) did not conduct tests to study torsional behavior, it is reasonable to apply λ_{duct} to the capacity calculation by Eq. 5.7.3.6.2-1 to be consistent with the fundamentals of the MCFT. In this way, shear resulting from torsion and that resulting from direct shear can be combined consistently in webs or flanges of members that contain post-tensioning ducts embedded in concrete.

5.7.3.4—Procedures for Determining Shear Resistance Parameters, β and θ

Design for shear may utilize either of the two methods identified herein provided that all requirements for usage of the chosen method are satisfied.

5.7.3.4.1—Simplified Procedure for Nonprestressed Sections

For concrete footings in which the distance from point of zero shear to the face of the column, pier, or wall is less than $3d_v$ with or without transverse reinforcement, and for other nonprestressed concrete sections not subjected to axial tension and containing at least the minimum amount of transverse reinforcement specified in Article 5.7.2.5, or having an overall depth of less than 16.0 in., the following values may be used:

$$\begin{aligned}\beta &= 2.0 \\ \theta &= 45 \text{ degrees}\end{aligned}$$

5.7.3.4.2—General Procedure

The parameters β and θ may be determined either by the provisions herein, or alternatively by the provisions of Appendix B5.

For sections containing at least the minimum amount of transverse reinforcement specified in Article 5.7.2.5, the value of β may be determined by Eq. 5.7.3.4.2-1:

$$\beta = \frac{4.8}{(1 + 750\varepsilon_s)} \quad (5.7.3.4.2-1)$$

When sections do not contain at least the minimum amount of shear reinforcement, the value of β may be as specified in Eq. 5.7.3.4.2-2:

$$\beta = \frac{4.8}{(1 + 750\varepsilon_s)} \frac{51}{(39 + s_{sv})} \quad (5.7.3.4.2-2)$$

The value of θ in both cases may be as specified in Eq. 5.7.3.4.2-3:

$$\theta = 29 + 3500\varepsilon_s \quad (5.7.3.4.2-3)$$

In Eqs. 5.7.3.4.2-1 through 5.7.3.4.2-3, ε_s is the net longitudinal tensile strain in the section at the centroid of the tension reinforcement as shown in Figures 5.7.3.4.2-1

C5.7.3.4

Two complementary methods are given for evaluating shear resistance. Method 1, specified in Article 5.7.3.4.1, as described herein, is only applicable for nonprestressed sections. Method 2, as described in Article 5.7.3.4.2, is applicable for all prestressed and nonprestressed members, with and without shear reinforcement, with and without axial load. Two approaches are presented in Method 2: a direct calculation, specified in Article 5.7.3.4.2, and an evaluation using tabularized values presented in Appendix B5. The approaches to Method 2 may be considered statistically equivalent.

C5.7.3.4.1

With β taken as 2.0 and θ as 45 degrees, the expressions for shear strength become essentially identical to those traditionally used for evaluating shear resistance. Recent large-scale experiments (Shioya et al., 1989), however, have demonstrated that these traditional expressions can be seriously unconservative for large members not containing transverse reinforcement.

C5.7.3.4.2

The shear resistance of a member may be determined by performing a detailed sectional analysis that satisfies the requirements of Article 5.7.3.1. Such an analysis, see Figure C5.7.3.4.2-1, would show that the shear stresses are not uniform over the depth of the web and that the direction of the principal compressive stresses changes over the depth of the beam. The more direct procedure given herein assumes that the concrete shear stresses are uniformly distributed over an area b_v wide and d_v deep, that the direction of principal compressive stresses, defined by angle θ , remains constant over d_v , and that the shear strength of the section can be determined by considering the biaxial stress conditions at just one location in the web. See Figure C5.7.3.4.2-2.

This design procedure (Collins et al, 1996) was derived from the MCFT (Vecchio and Collins, 1986) which is a comprehensive behavioral model for the response of diagonally cracked concrete subject to in-plane shear and normal stresses. Prior to the 2008 interim revisions, the General Procedure for shear design was iterative and required the use of tables for the evaluation of β and θ . With the 2008 revisions, this design procedure was modified to be noniterative and algebraic equations were introduced for the evaluation of β and θ . These equations are functionally equivalent to those used in the Canadian design code (CSA-A23.3-M04, 2004), were

and 5.7.3.4.2-2. In lieu of more involved procedures, ϵ_s may be determined by Eq. 5.7.3.4.2-4:

$$\epsilon_s = \frac{\left(\frac{|M_u|}{d_v} + 0.5N_u + |V_u - V_p| - A_{ps}f_{po} \right)}{E_s A_s + E_p A_{ps}} \quad (5.7.3.4.2-4)$$

Where consideration of torsion is required by the provisions of Article 5.7.2.1, V_u in Eq. 5.7.3.4.2-4 shall be replaced by V_{eff} .

For solid sections:

$$V_{eff} = \sqrt{V_u^2 + \left(\frac{0.9p_h T_u}{2A_o} \right)^2} \quad (5.7.3.4.2-5)$$

For hollow sections:

$$V_{eff} = V_u + \frac{T_u d_s}{2A_o} \quad (5.7.3.4.2-6)$$

where:

- $|M_u|$ = absolute value of the factored moment at the section, not taken less than $|V_u - V_p|d_v$ (kip-in.)
- N_u = factored axial force, taken as positive if tensile and negative if compressive (kip)
- V_u = factored shear force for the girder in Eq. 5.7.3.4.2-5 and for the web under consideration in Eq. 5.7.3.4.2-6 (kip)
- A_{ps} = area of prestressing steel on the flexural tension side of the member, as shown in Figure 5.7.3.4.2-1 (in.²)
- f_{po} = a parameter taken as modulus of elasticity of prestressing steel multiplied by the locked-in difference in strain between the prestressing steel and the surrounding concrete (ksi). For the usual levels of prestressing, a value of $0.7 f_{pu}$ will be appropriate for both pretensioned and post-tensioned members
- p_h = perimeter of the centerline of the closed transverse torsion reinforcement (in.)
- T_u = applied factored torsional moment on the girder (kip-in.)
- A_o = area enclosed by the shear flow path, including any area of holes therein (in.²)
- d_s = distance from extreme compression fiber to the centroid of the nonprestressed tensile reinforcement measured along the centerline of the web (in.)
- A_{ct} = area of concrete on the flexural tension side of the member as shown in Figure 5.7.3.4.2-1 (in.²)
- A_s = area of nonprestressed steel on the flexural tension side of the member at the section under

also derived from the MCFT (Bentz et al., 2006), and were evaluated as appropriate for use in the AASHTO LRFD Bridge Design Specifications (Hawkins and Kuchma, 2007) (Hawkins et al., 2005).

For solid cross-section shapes, such as a rectangle or an "I," there is the possibility of considerable redistribution of shear stresses. To make some allowance for this favorable redistribution, it is safe to use a root-mean-square approach in calculating the nominal shear stress for these cross-sections, as indicated in Eq. 5.7.3.4.2-5. The $0.9p_h$ comes from 90 percent of the perimeter of the spalled concrete section. This is similar to multiplying 0.9 times the lever arm in flexural calculations.

For a hollow girder, where it is required to consider torsion, the shear flow due to torsion is added to the shear flow due to flexure in one exterior web, and subtracted from the opposite exterior web. The possibility of reversed torsion should be investigated. In the controlling web, the second term in Eq. 5.7.3.4.2-6 comes from integrating the distance from the centroid of the section, to the center of the shear flow path around the circumference of the section. The stress is converted to a force by multiplying by the web height measured between the shear flow paths in the top and bottom slabs, which has a value approximately equal that of d_s .

The longitudinal strain, ϵ_s , can be determined by the procedure illustrated in Figure C5.7.3.4.2-3. The actual section is represented by an idealized section consisting of a flexural tension flange, a flexural compression flange, and a web. The area of the compression flange is taken as the area on the flexure compression side of the member, i.e., the total area minus the area of the tension flange as defined by A_{ct} . After diagonal cracks have formed in the web, the shear force applied to the web concrete, $V_u - V_p$, will primarily be carried by diagonal compressive stresses in the web concrete.

These diagonal compressive stresses will result in a longitudinal compressive force in the web concrete of $(V_u - V_p) \cot \theta$. Equilibrium requires that this longitudinal compressive force in the web needs to be balanced by tensile forces in the two flanges, with half the force, that is $0.5 (V_u - V_p) \cot \theta$, being taken by each flange. For simplicity, $0.5 \cot \theta$ may be taken as equal to 1.0 and the longitudinal demand due to shear in the longitudinal tension reinforcement becomes $V_u - V_p$ without significant loss of accuracy. After the required axial forces in the two flanges are calculated, the resulting axial strains, ϵ_s and ϵ_c , can be calculated based on the axial force-axial strain relationship shown in Figure C5.7.3.4.2-4.

For pretensioned members, f_{po} can be taken as the stress in the strands when the concrete is cast around them, i.e., approximately equal to the jacking stress. For post-tensioned members, f_{po} can be conservatively taken as the average stress in the tendons when the post-tensioning is completed.

ϵ_s which is greater than that calculated from Eq. 5.7.3.4.2-4. However, ϵ_s should not be taken greater than 6.0×10^{-3} .

Figure 5.7.3.4.2-1—Illustration of Shear Parameters for Section Containing at Least the Minimum Amount of Transverse Reinforcement, $V_p = 0$

Figure 5.7.3.4.2-2—Longitudinal Strain, ϵ_s , for Sections Containing Less than the Minimum Amount of Transverse Reinforcement

Figure 5.7.3.4.2-3—Definition of Crack Spacing Parameter, s_x

The relationships for evaluating β and θ in Eqs. 5.7.3.4.2-1 and 5.7.3.4.2-2 are based on calculating the stresses that can be transmitted across diagonally cracked concrete. As the cracks become wider, the stress that can be transmitted decreases. For members containing at least the minimum amount of transverse reinforcement, it is assumed that the diagonal cracks will be spaced about 12.0 in. apart. For members without transverse reinforcement, the spacing of diagonal cracks inclined at θ degrees to the longitudinal reinforcement is assumed to be $s_x / \sin \theta$, as shown in Figure 5.7.3.4.2-3. Hence, deeper members having larger values of s_x are calculated to have more widely spaced cracks and, hence, cannot transmit such high shear stresses. The ability of the crack surfaces to transmit shear stresses is influenced by the aggregate size of the concrete. Members made from concretes that have a smaller maximum aggregate size will have a larger value of s_{xe} and hence, if there is no transverse reinforcement, will have a smaller shear strength.

Figure C5.7.3.4.2-3—More Accurate Calculation Procedure for Determining ϵ_s

Figure C5.7.3.4.2-4—Assumed Relationships between Axial Force in Flange and Axial Strain of Flange

5.7.3.5—Longitudinal Reinforcement

Where consideration of torsion is required these provisions shall be amended as specified in Article 5.7.3.6.3.

Except as specified herein, at each section the tensile capacity of the longitudinal reinforcement on the flexural tension side of the member shall be proportioned to satisfy:

$$A_{ps} f_{ps} + A_s f_y \geq \frac{|M_u|}{d_v \phi_f} + 0.5 \frac{N_u}{\phi_c} + \left(\left(\frac{V_u}{\phi_v} - V_p \right) - 0.5 V_s \right) \cot \theta \quad (5.7.3.5-1)$$

where:

- ϕ_f, ϕ_v, ϕ_c = resistance factors taken from Article 5.5.4.2 as appropriate for moment, shear, and axial resistance
- V_s = shear resistance provided by transverse reinforcement at the section under investigation as given by Eq. 5.7.3.3-4, except V_s shall not be taken as greater than V_u / ϕ_v in Eqs. 5.7.3.5-1 and 5.7.3.5-2 (kip)

C5.7.3.5

Shear causes tension in the longitudinal reinforcement. For a given shear, this tension becomes larger as θ becomes smaller and as V_c becomes larger.

The tension in the longitudinal reinforcement caused by the shear force can be visualized from a free-body diagram such as that shown in Figure C5.7.3.5-1. Taking moments about the compression force C in Figure C5.7.3.5-1, assuming that the aggregate interlock force on the crack, which contributes to V_c , has a negligible moment about the compression force C, and neglecting the small difference in location of V_u and V_p leads to the requirement for the tension force in the longitudinal reinforcement caused by shear.

θ = angle of inclination of diagonal compressive stresses used in determining the nominal shear resistance of the section under investigation as determined by Article 5.7.3.4 (degrees)

Figure C5.7.3.5-1—Forces Assumed in Resistance Model Caused by Moment and Shear

Eq. 5.7.3.5-1 shall be evaluated where simply-supported girders are made continuous for live loads and where longitudinal reinforcement is discontinuous.

At the inside edge of the bearing area of simple end supports to the section of critical shear, the longitudinal reinforcement on the flexural tension side of the member shall satisfy:

$$A_s f_y + A_{ps} f_{ps} \geq \left(\frac{V_u}{\phi_v} - 0.5V_s - V_p \right) \cot \theta \quad (5.7.3.5-2)$$

Eqs. 5.7.3.5-1 and 5.7.3.5-2 shall be taken to apply to sections not subjected to torsion. Any lack of full development shall be accounted for.

For pretensioned sections, including those with debonded strands, the tensile force in the prestressing reinforcement, $A_{ps} f_{ps}$, shall exceed the tensile forces of the nonprestressed reinforcement, $A_s f_y$, at all sections. Development of straight and bent-up strands as well as overhangs, if present, shall be considered for determining the value of $A_{ps} f_{ps}$ and $A_s f_y$.

Except as may be required by Article 5.7.3.6.3, where the reaction force or the load at the maximum moment location introduces direct compression into the flexural compression face of the member, the area of longitudinal reinforcement on the flexural tension side of the member need not exceed the area required to resist the maximum moment acting alone.

In determining the tensile force that the reinforcement is expected to resist at the inside edge of the bearing area, the values of V_u , V_s , V_p , and θ , calculated for the section d_v from the face of the support may be used. In calculating the tensile resistance of the longitudinal reinforcement, a linear variation of resistance over the development length of Article 5.10.8.2.1a or the bi-linear variation of resistance over the transfer and development length of Article 5.9.4.3.2 may be assumed.

At maximum moment locations, the shear force changes sign, and hence the inclination of the diagonal compressive stresses changes. At direct supports including simply-supported girder ends and bent/pier caps pinned to columns, and at loads applied directly to the top or bottom face of the member, this change of inclination is associated with a fan-shaped pattern of compressive stresses radiating from the point load or the direct support as shown in Figure C5.7.3.5-2. This fanning of the diagonal stresses reduces the tension in the longitudinal reinforcement caused by the shear; i.e., angle θ becomes steeper. The tension in the reinforcement does not exceed that due to the maximum moment alone. Hence, the longitudinal reinforcement requirements can be met by extending the flexural reinforcement for a distance of $d_v \cot \theta$ or as specified in Article 5.10.8, whichever is greater.

Figure C5.7.3.5-2—Force Variation in Longitudinal Reinforcement Near Maximum Moment Locations

Longitudinal or transverse reinforcing steel, or a combination thereof, with specified minimum yield strengths up to 100 ksi, may be used in elements and connections specified in Article 5.4.3.3.

5.7.3.6—Sections Subjected to Combined Shear and Torsion

5.7.3.6.1—Transverse Reinforcement

The transverse reinforcement shall not be less than the sum of that required for shear, as specified in Article 5.7.3.3, and for the concurrent torsion, as specified in Articles 5.7.2.1 and 5.7.3.6.2.

C5.7.3.6.1

The shear stresses due to torsion and shear will add on one side of the section and offset on the other side. The transverse reinforcement is designed for the side where the effects are additive.

Usually the loading that causes the highest torsion differs from the loading that causes the highest shear. Although it is sometimes convenient to design for the highest torsion combined with the highest shear, it is only necessary to design for the highest shear and its concurrent torsion, and the highest torsion and its concurrent shear.

5.7.3.6.2—Torsional Resistance

The nominal torsional resistance shall be taken as:

$$T_n = \frac{2A_o A_t f_y \cot \theta}{s} \lambda_{duct} \quad (5.7.3.6.2-1)$$

where:

A_o = area enclosed by the shear flow path, including any area of holes therein (in.²)

A_t = area of one leg of closed transverse torsion reinforcement in solid members, or total area of transverse torsion reinforcement in the exterior web and flange of hollow members (in.²)

θ = angle of inclination of diagonal compressive stresses as determined in accordance with the

C5.7.3.6.2

See Article 5.7.2.4 for limits of the yield strength of transverse reinforcement.

For solid sections, A_o may be taken as the area enclosed by the centerline of the effective width b_e determined as A_{cp}/p_c , with A_{cp} and p_c taken as defined in Article 5.7.2.1.

For hollow members, the total area of transverse reinforcing, A_t must be placed in each exterior web and each flange that forms the closed shape.

- provisions of Article 5.7.3.4 with the modifications to the expressions for v and V_u herein (degrees)
- s = spacing of transverse reinforcement measured in a direction parallel to the longitudinal reinforcement (in.)
- λ_{duct} = shear strength reduction factor, as defined in Eq. 5.7.3.3-5

5.7.3.6.3—Longitudinal Reinforcement

The provisions of Article 5.7.3.5 shall apply as amended, herein, to include torsion. At least one bar or tendon shall be placed in the corners of the stirrups.

The longitudinal reinforcement in solid sections shall be proportioned to satisfy Eq. 5.7.3.6.3-1:

$$\frac{A_{ps} f_{ps} + A_s f_y}{\phi d_v} + \frac{0.5 N_u}{\phi} + \cot \theta \sqrt{\left(\left| \frac{V_u}{\phi} - V_p \right| - 0.5 V_s \right)^2 + \left(\frac{0.45 p_h T_u}{2 A_o \phi} \right)^2} \geq \quad (5.7.3.6.3-1)$$

In box sections, longitudinal reinforcement for torsion, in addition to that required for flexure, shall not be less than:

$$A_t = \frac{T_u p_h}{2 A_o f_y} \quad (5.7.3.6.3-2)$$

where:

- p_h = perimeter of the centerline of the closed transverse torsion reinforcement for solid members, or the perimeter through the centroids of the transverse torsion reinforcement in the exterior webs and flanges for hollow members (in.)

A_t shall be distributed around the outermost webs and top and bottom slabs of the box girder.

C5.7.3.6.3

To account for the fact that on one side of the section the torsional and shear stresses oppose each other, the equivalent tension used in the design equation is taken as the square root of the sum of the squares of the individually calculated tensions in the web.

Torsion addressed in this Article, St. Venant's torsion, causes an axial tensile force. In a nonprestressed beam, this force is resisted by longitudinal reinforcement having an axial tensile strength of $A_t f_y$. This steel is in addition to the flexural reinforcement and is to be distributed uniformly around the perimeter so that the resultant acts along the axis of the member. In a prestressed beam, the same approach (providing additional reinforcing bars with strength $A_t f_y$) can be followed, or the longitudinal torsion reinforcement can be comprised of normal reinforcing bars and any portion of the longitudinal prestressing steel in excess of that required for cross-sectional flexural resistance at the strength limit states.

For box girder construction, interior webs should not be considered in the calculation of the longitudinal torsion reinforcement required by this Article. The values of p_h and A_t should be for the box shape defined by the outer-most webs and the top and bottom slabs of the box girder. Warping torsion is known to exist in cross-section (d) shown in Table 4.6.2.2.1-1, but many structures of this type have performed successfully without consideration of warping.

The longitudinal tension due to torsion may be considered to be offset in part by compression at a cross-section resulting from longitudinal flexure, allowing a reduction in the longitudinal torsion steel in longitudinally compressed portions of the cross-section at strength limit states.

5.7.4—Interface Shear Transfer—Shear Friction

5.7.4.1—General

Interface shear transfer shall be considered across a given plane at:

- An existing or potential crack;
- An interface between dissimilar materials;
- An interface between two concretes cast at different times; or

C5.7.4.1

Shear displacement along an interface plane may be resisted by cohesion, aggregate interlock, and shear-friction developed by the force in the reinforcement crossing the plane of the interface. Roughness of the shear plane causes interface separation in a direction perpendicular to the interface plane. This separation induces tension in the reinforcement balanced by compressive stresses on the interface surfaces.

- The interface between different elements of the cross-section.

Where the required interface shear reinforcement in girder/slab design exceeds the area required to satisfy flexural shear requirements, additional reinforcement shall be provided to satisfy the interface shear requirements. The additional interface shear reinforcement need only extend into the girder a sufficient depth to develop the design yield stress of the reinforcement rather than extending the full depth of the girder as is required for vertical shear reinforcement.

Reinforcement for interface shear may consist of single bars, multiple leg stirrups, or welded wire reinforcement.

All reinforcement present where interface shear transfer is to be considered shall be fully developed on both sides of the interface by embedment, hooks, mechanical methods such as headed studs, or welding to develop the design yield stress.

5.7.4.2—Minimum Area of Interface Shear Reinforcement

Except as provided herein, the cross-sectional area of the interface shear reinforcement, A_{vf} , crossing the interface area, A_{cv} , shall satisfy:

$$A_{vf} \geq \frac{0.05 A_{cv}}{f_y} \quad (5.7.4.2-1)$$

where:

- A_{vf} = area of interface shear reinforcement crossing the shear plane within the area A_{cv} (in.²)
- A_{cv} = area of concrete considered to be engaged in interface shear transfer (in.²)
- f_y = yield stress of reinforcement but design value not to exceed 60.0 (ksi)

For a cast-in-place concrete slab on clean concrete girder surfaces free of laitance, the following provisions shall apply:

- The minimum interface shear reinforcement, A_{vf} , need not exceed the lesser of the amount determined using Eq. 5.7.4.2-1 and the amount needed to resist $1.33V_{ui}/\phi$ as determined using Eq. 5.7.4.3-3.

Any reinforcement crossing the interface is subject to the same strain as the designed interface reinforcement. Insufficient anchorage of any reinforcement crossing the interface could result in localized fracture of the surrounding concrete.

C5.7.4.2

For a girder/slab interface, the minimum area of interface shear reinforcement per foot of girder length is calculated by replacing A_{cv} in Eq. 5.7.4.2-1 with $12b_{vf}$.

Previous editions of these Specifications have required a minimum area of reinforcement based on the full interface area; similar to Eq. 5.7.4.2-1, irrespective of the need to mobilize the strength of the full interface area to resist the applied factored interface shear. In 2006, the additional minimum area provisions, applicable only to girder/slab interfaces, were introduced. The intent of these provisions was to eliminate the need for additional interface shear reinforcement due simply to a beam with a wider top flange being utilized in place of a narrower-flanged beam.

The additional provision establishes a rational upper bound for the area of interface shear reinforcement required based on the interface shear demand rather than the interface area as stipulated by Eq. 5.7.4.2-1. This

- The minimum reinforcement provisions specified herein shall be waived for girder/slab interfaces with surface roughened to an amplitude of 0.25 in. where the factored interface shear stress, V_{ui} , of Eq. 5.7.4.5-1, is less than 0.210 ksi, and all vertical (transverse) shear reinforcement required by the provisions of Article 5.7.2.5 is extended across the interface and adequately anchored in the slab.

5.7.4.3—Interface Shear Resistance

The factored interface shear resistance, V_{ri} , shall be taken as:

$$V_{ri} = \phi V_{ni} \quad (5.7.4.3-1)$$

and the design shall satisfy:

$$V_{ri} \geq V_{ui} \quad (5.7.4.3-2)$$

where:

ϕ = resistance factor for shear, specified in Article 5.5.4.2. For the extreme limit state, event ϕ may be taken as 1.0.

V_{ni} = nominal interface shear resistance (kip)

V_{ui} = factored interface shear force due to total load based on the applicable strength and extreme event load combinations in Table 3.4.1-1 (kip)

The nominal shear resistance of the interface plane shall be taken as:

$$V_{ni} = cA_{cv} + \mu (A_{vf} f_v + P_c) \quad (5.7.4.3-3)$$

The nominal shear resistance, V_{ni} , used in the design shall not exceed either of the following:

$$V_{ni} \leq K_1 f_c A_{cv} \quad (5.7.4.3-4)$$

$$V_{pi} \leq K_2 A_{cv} \quad (5.7.4.3-5)$$

in which:

$$A_{cy} = b_{yi} L_{yi} \quad (5.7.4.3-6)$$

treatment is analogous to minimum reinforcement provisions for flexural capacity where a minimum additional overstrength factor of 1.33 is required beyond the factored demand.

With respect to a girder/slab interface, the intent is that the portion of the reinforcement required to resist vertical shear which is extended into the slab also serves as interface shear reinforcement.

C5.7.4.3

Total load shall include all noncomposite and composite loads appropriate to the interface being investigated.

A pure shear friction model assumes interface shear resistance is directly proportional to the net normal clamping force ($A_v f_y + P_c$), through a friction coefficient (μ). Eq. 5.7.4.3-3 is a modified shear-friction model accounting for a contribution, evident in the experimental data, from cohesion and/or aggregate interlock depending on the nature of the interface under consideration given by the first term. For simplicity, the term “cohesion factor” is used throughout the body of this article to capture the effects of cohesion and/or aggregate interlock such that Eq. 5.7.4.3-3 is analogous to the vertical shear resistance expression of $V_c + V_s$.

Eq. 5.7.4.3-4 limits V_{ni} to prevent crushing or shearing of aggregate along the shear plane.

Eqs. 5.7.4.3-3 and 5.7.4.3-4 are sufficient, with an appropriate value for K_1 , to establish a lower bound for the available experimental data; however, Eq. 5.7.4.3-5 is necessitated by the sparseness of available experimental data beyond the limiting K_2 values provided in Article 5.7.4.4.

The interface shear strength Eqs. 5.7.4.3-3, 5.7.4.3-4, and 5.7.4.3-5 are based on experimental data for normal weight, nonmonolithic concrete strengths

where:

- c = cohesion factor, specified in Article 5.7.4.4 (ksi)
 μ = friction factor, specified in Article 5.7.4.4
 b_{vi} = interface width considered to be engaged in shear transfer (in.)
 L_{vi} = interface length considered to be engaged in shear transfer (in.)

P_c = net compressive force due to unfactored permanent force effects, normal to the shear plane; if force is tensile, $P_c = 0.0$ (kip)

- f'_c = design concrete compressive strength of the weaker concrete on either side of the interface (ksi)
 K_1 = fraction of concrete strength available to resist interface shear, as specified in Article 5.7.4.4.
 K_2 = limiting interface shear resistance specified in Article 5.7.4.4 (ksi)

If a member has transverse reinforcement with a specified minimum yield strength greater than 60.0 ksi for flexural shear resistance, interface reinforcement may be provided by extending the transverse reinforcement across the interface zone. In this case, the value of f_y in Eq. 5.7.4.3-3 shall not be taken as greater than 60.0 ksi.

5.7.4.4—Cohesion and Friction Factors

The following values shall be taken for cohesion, c , and friction factor, μ :

- For a cast-in-place concrete slab on clean concrete girder surfaces, free of laitance with surface roughened to an amplitude of 0.25 in.

- c = 0.28 ksi
 μ = 1.0
 K_1 = 0.3
 K_2 = 1.8 ksi for normal weight concrete
= 1.3 ksi for lightweight concrete

ranging from 2.5 ksi to 16.5 ksi; normal weight, monolithic concrete strengths from 3.5 ksi to 18.0 ksi; and lightweight concrete strengths from 2.0 ksi to 6.0 ksi.

A_{vf} used in Eq. 5.7.4.3-3 is the interface shear reinforcement within the interface area A_{cv} . For a girder/slab interface, the area of the interface shear reinforcement per foot of girder length is calculated by replacing A_{cv} in Eq. 5.7.4.3-3 with $12b_{vi}$ and P_c corresponding to the same one foot of girder length.

In consideration of the use of stay-in-place deck panels, or any other interface details, the Designer shall determine the width of interface, b_{vi} , effectively acting to resist interface shear.

The interface reinforcement is assumed to be stressed to its design yield stress, f_y . However, f_y used in determining the interface shear resistance is limited to 60.0 ksi because interface shear resistance computed using higher values have overestimated the interface shear resistance experimentally determined in a limited number of tests of precracked specimens.

It is conservative to neglect P_c if it is compressive, however, if included, the value of P_c shall be computed as the force acting over the area, A_{cv} . If P_c is tensile, additional reinforcement is required to resist the net tensile force as specified in Article 5.7.4.5.

C5.7.4.4

The values presented provide a lower bound of the substantial body of experimental data available in the literature (Loov and Patnaik, 1994) (Patnaik, 1999) (Mattock, 2001) (Kahn and Slapkus, 2004). Furthermore, the inherent redundancy of girder/slab bridges distinguishes this system from other structural interfaces.

- For normal weight concrete placed monolithically:

$$\begin{aligned}c &= 0.40 \text{ ksi} \\ \mu &= 1.4 \\ K_1 &= 0.25 \\ K_2 &= 1.5 \text{ ksi}\end{aligned}$$

- For lightweight concrete placed monolithically, or placed against a clean concrete surface, free of laitance with surface intentionally roughened to an amplitude of 0.25 in.:

$$\begin{aligned}c &= 0.24 \text{ ksi} \\ \mu &= 1.0 \\ K_1 &= 0.25 \\ K_2 &= 1.0 \text{ ksi}\end{aligned}$$

- For normal weight concrete placed against a clean concrete surface, free of laitance, with surface intentionally roughened to an amplitude of 0.25 in.:

$$\begin{aligned}c &= 0.24 \text{ ksi} \\ \mu &= 1.0 \\ K_1 &= 0.25 \\ K_2 &= 1.5 \text{ ksi}\end{aligned}$$

- For concrete placed against a clean concrete surface, free of laitance, but not intentionally roughened:

$$\begin{aligned}c &= 0.075 \text{ ksi} \\ \mu &= 0.6 \\ K_1 &= 0.2 \\ K_2 &= 0.8 \text{ ksi}\end{aligned}$$

- For concrete anchored to as-rolled structural steel by headed studs or by reinforcing bars where all steel in contact with concrete is clean and free of paint:

$$\begin{aligned}c &= 0.025 \text{ ksi} \\ \mu &= 0.7 \\ K_1 &= 0.2 \\ K_2 &= 0.8 \text{ ksi}\end{aligned}$$

For brackets, corbels, and ledges, the cohesion factor, c , shall be taken as 0.0.

The values presented apply strictly to monolithic concrete. These values are not applicable for situations where a crack may be anticipated to occur at a service limit state.

The factors presented provide a lower bound of the experimental data available in the literature (Hofbeck, Ibrahim, and Mattock, 1969) (Mattock, Li, and Wang, 1976) (Kahn and Mitchell, 2002).

Available experimental data demonstrates that only one modification factor is necessary, when coupled with the resistance factors of Article 5.5.4.2, to accommodate lightweight concrete with lightweight fine aggregate and normal weight fine aggregate. This deviates from earlier specifications that distinguished between different types of lightweight concrete.

Due to the absence of existing data, the prescribed cohesion and friction factors for lightweight concrete placed against hardened concrete are accepted as conservative for application to monolithic lightweight concrete.

Tighter constraints have been adopted for roughened interfaces, other than cast-in-place slabs on roughened girders, even though available test data does not indicate more severe restrictions are necessary. This is to account for variability in the geometry, loading, and lack of redundancy at other interfaces.

Since the effectiveness of cohesion and aggregate interlock along a vertical crack interface is unreliable, the cohesion component in Eq. 5.7.4.3-3 is set to 0.0 for brackets, corbels, and ledges.

5.7.4.5—Computation of the Factored Interface Shear Force for Girder/Slab Bridges

Based on consideration of a free body diagram and utilizing the conservative envelope value of V_{u1} , the factored interface shear stress for a concrete girder/slab bridge may be determined as:

$$V_{ui} = \frac{V_{u1}}{b_{vi} d_v} \quad (5.7.4.5-1)$$

where:

d_v = distance between the centroid of the tension steel and the mid-thickness of the slab to compute a factored interface shear stress (in.)

The factored interface shear force in kips/ft for a concrete girder/slab bridge may be determined as:

$$V_{ui} = v_{ui} A_{cv} = v_{ui} 12b_{vi} \quad (5.7.4.5-2)$$

If the net force, P_c , across the interface shear plane is tensile, additional reinforcement, A_{vpc} , shall be provided as:

$$A_{vpc} = \frac{P_c}{\phi f_y} \quad (5.7.4.5-3)$$

C5.7.4.5

The following illustrates a free body diagram approach to computation of interface shear in a girder/slab bridge. In reinforced concrete, or prestressed concrete, girder bridges, with a cast-in-place slab, horizontal shear forces develop along the interface between the girders and the slab. The classical strength of materials approach, which is based on elastic behavior of the section, has been used successfully in the past to determine the design interface shear force. As an alternative to the classical elastic strength of materials approach, a reasonable approximation of the factored interface shear force at the strength or extreme event limit state for either elastic or inelastic behavior and cracked or uncracked sections, can be derived with the defined notation and the free body diagram shown in Figure C5.7.4.5-1 as follows:

M_{u2} = maximum factored moment at section 2 (kip-in.)

V_1 = factored vertical shear at section 1 concurrent with M_{u2} (kip)

M_1 = factored moment at section 1 concurrent with M_{u2} (kip-in.)

$\Delta \ell$ = unit length segment of girder (in.)

C_1 = compression force above the shear plane associated with M_1 (kip)

C_{u2} = compression force above the shear plane associated with M_{u2} (kip)

$$M_{u2} = M_1 + V_1 \Delta \ell \quad (C5.7.4.5-1)$$

$$C_{u2} = \frac{M_{u2}}{d_v} \quad (C5.7.4.5-2)$$

$$C_{u2} = \frac{M_1}{d_v} + \frac{V_1 \Delta \ell}{d_v} \quad (C5.7.4.5-3)$$

$$C_1 = \frac{M_1}{d_v} \quad (C5.7.4.5-4)$$

For beams or girders, the longitudinal center-to-center spacing of nonwelded interface shear connectors shall not exceed 48.0 in. or the depth of the member, h . For cast-in-place box girders, the longitudinal center-to-center spacing of nonwelded interface shear connectors shall not exceed 24.0 in.

Research (Markowski et al., 2005) (Tadros and Girgis, 2006) (Badié and Tadros, 2008) (Sullivan et al., 2011) has demonstrated that increasing interface shear connector spacing from 24.0 to 48.0 in. has resulted in no deficiency in composite action for the same resistance of shear connectors per foot, and girder and deck configurations. These research projects have independently demonstrated no vertical separation between the girder top and the deck under cyclic or ultimate loads. However, the research did not investigate relatively shallow members; hence, the additional limitation related to the member depth is provided.

As the spacing of connector groups increases, the capacities of the concrete and grout in their vicinity become more critical and need to be carefully verified. This applies to all connected elements at the interface. Eqs. 5.7.4.3-2 and 5.7.4.3-3 are intended to ensure that the capacity of the concrete component of the interface is adequate. Methods to enhance that capacity, if needed, include use of high-strength materials and of localized confinement reinforcement.

5.7.4.6—Interface Shear in Box Girder Bridges

Adequate shear transfer reinforcement shall be provided at the web/flange interfaces in box girders to transfer flange longitudinal forces at the strength limit state. Consideration shall be given to any construction joints at the interfaces, as well as the amount of reinforcing present in the flange and web for other design purposes.

C5.7.4.6

The factored design force for the interface reinforcement is calculated to account for the interface shear force as well as any localized shear effects due to the prestressing force anchorages at the section.

Historically, vertical planes at the web/flange interface have been checked for segmental bridges. If a horizontal construction joint is present, the interface shear check should also include the horizontal planes at the construction joints. This is a check that enough reinforcing is present. Additional reinforcing need not be added if there is already enough reinforcing present for other purposes, such as global shear and torsion in the cross-section and transverse bending.

5.8—DESIGN OF D-REGIONS

5.8.1—General

Refined analysis methods or STMs may be used to determine internal force effects in disturbed regions such as those near supports and the points of application of concentrated loads at strength and extreme event limit states.

5.8.2—Strut-and-Tie Method (STM)

5.8.2.1—General

The STM may be used to determine internal force effects near supports and the points of application of concentrated loads at strength and extreme event limit states.

C5.8.2.1

Traditional section-by-section design is based on the assumption that the reinforcement required at a particular section depends only on the independent values of the factored section force effects V_u , M_u , and

The STM should be considered for the design of deep footings and pile caps or other situations in which the distance between the centers of applied load and the supporting reactions is less than two times the member depth.

The provisions of these articles apply to components with reinforcement yield strengths not exceeding 75.0 ksi, and design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi.

The STM provisions herein were developed for nonhydrostatic nodes and shall not be applied to strut-and-tie models utilizing hydrostatic nodes.

Where the STM is selected for structural analysis, Articles 5.8.2.2 through 5.8.2.6 shall apply. For post-tensioning anchorage zones, diaphragms, deep beams, brackets, beam ledges and corbels, Articles 5.8.2.7 through 5.8.2.9 and 5.8.4 shall also apply.

T_{12} , and does not consider the manner in which the loads and reactions that generate these sectional forces are applied. The traditional method further assumes that the shear stress distribution is essentially uniform over the depth and that the longitudinal strains will vary linearly over the depth of the beam.

For members such as deep beams, these assumptions are not valid. For example, the shear stresses on a section near a support will be concentrated near the bottom face. The behavior of a component can be predicted more accurately if the flow of forces through the complete structure is studied.

The STM is a conceptual design approach based on load paths. While the majority of experimental verification is limited to elements constructed with normal weight concrete, the STM can reasonably be assumed to be suitable for design of lightweight concrete elements.

The STM provisions herein allow a more seamless transition between B- and D-Regions of a given structure. This is accomplished by replacing the previous strain-based strut efficiency calculations with newly developed efficiency factors based primarily upon the *fib Model Code for Concrete Structures 2010*. The new efficiency factors are simpler to use; less open to misinterpretation; and exhibit better statistical parameters, bias, and coefficients of variation, leading to improved accuracy and precision in a variety of applications documented by Birrcher et al. (2009), Williams et al. (2012), and Larson et al. (2013). These provisions and five other design methods are compared to 179 experimental results in Birrcher et al. (2009).

The geometry of each node should be defined prior to conducting the strength checks. Nodes may be proportioned in two ways: (1) as hydrostatic nodes or (2) as nonhydrostatic nodes. Hydrostatic nodes are proportioned in a manner that causes the stresses applied to each face to be equal. Nonhydrostatic nodes, however, are proportioned based on the origin of the applied stress. For example, the faces of a nonhydrostatic node may be sized to match the depth of the equivalent rectangular compression stress block of a flexural member or may be based upon the desired location of the longitudinal reinforcement (see Figure C5.8.2.1-1). This proportioning technique allows the geometry of the nodes to closely correspond to the actual stress concentrations at the nodal regions. In contrast, the use of hydrostatic nodes can sometimes result in unrealistic nodal geometries and impractical reinforcement layouts as shown in Figure C5.8.2.1-1. Thus, nonhydrostatic nodes are preferred in design and are used throughout these Specifications.

Figure C5.8.2.1-1—Hydrostatic and Nonhydrostatic Nodes

The basic steps in the STM may be taken as:

1. Determine the locations of the B- and D-Regions.
2. Define load cases.
3. Analyze structural components.
4. Size structural components using the shear serviceability check, given by Eq. C5.8.2.2-1.
5. Develop a strut-and-tie model. See Article 5.8.2.2.
6. Proportion ties.
7. Perform nodal strength checks. See Article 5.8.2.5.
8. Proportion crack control reinforcement. See Article 5.8.2.6.
9. Provide necessary anchorage for ties.

More detailed information on this method is given by Schlaich et al. (1987), Collins and Mitchell (1991), Martin and Sanders (2007), Birrcher et al. (2009), Mitchell and Collins (2013), Williams et al. (2012), and Larson et al. (2013).

5.8.2.2—Structural Modeling

The structure, and a component or region thereof, may be modeled as an assembly of steel ties and concrete struts interconnected at nodes to form a truss capable of carrying all the applied loads to the supports. As illustrated in Figure 5.8.2.2-1, nodes may be characterized as:

- CCC: nodes where only struts intersect
- CCT: nodes where a tie intersects the node in only one direction
- CTT: nodes where ties intersect in two different directions

The angle between the axes of a strut-and-tie shall be limited to angles greater than 25 degrees.

C5.8.2.2

Cracked reinforced concrete carries load principally by compressive stresses in the concrete and tensile stresses in the reinforcement. The principal compressive stress trajectories in the concrete can be approximated by straight struts. Ties are used to model the primary reinforcement.

The following general guidelines for model development should be considered:

- At the interface of a B-Region and a D-Region, ensure the internal forces and moment within the B-Region are applied correctly to the D-Region.
- A tie must be located at the centroid of the reinforcement that carries the tensile force.
- Minimize the number of vertical ties between a load and a support using the least number of truss panels possible while still satisfying the 25-degree minimum, as shown in Figure C5.8.2.2-3.
- The STM must be in external and internal equilibrium.
- Ensure proper reinforcement detailing.

The angular limits are provided in order to mitigate wide crack openings and excessive strain in the reinforcement. When the angular limit cannot be

- h_a = length of the back face of an STM node (in.)
 ℓ_a = effective length of a CTT node (in.)
 ℓ_b = length of the bearing face (in.)
 α = fraction defining the bearing face length of a portion of a nodal region
 θ_s = angle between strut and longitudinal axis of the member (degrees)

Figure 5.8.2.2-1—Nodal Geometries

If a D-Region is built in stages, forces imposed by each stage of construction on previously completed portions of the structure shall be carried through appropriate strut-and-tie models. Where a strut passes through a cold joint in the member, the joint shall be investigated to determine that it has sufficient shear-friction capacity. The strut force may be resolved into a

satisfied, the truss configuration should be altered as appropriate.

The consideration of shear-friction at cold joints is required for the strength of struts in STMs (FIP Commission 3, 1999).

A curved bar node, resulting from bending larger bars such as #11 and 18, is discussed in the literature and may also be considered where a review indicates that it is appropriate (Williams et al., 2012). This type of node, shown in Figure C5.8.2.2-1, is not yet included in the specification as it is not as well vetted by experimental data as the CCC, CCT, and CTT nodes.

Figure C5.8.2.2-1—Curved-Bar Node

For a CCT or CTT node, the tie width, or the available length, ℓ_a , over which the stirrups considered to carry the force in the tie can be spread, is indicated in Figure C5.8.2.2-2. The diagonal struts extending from both the load and the support are assumed to spread to form the fan shapes shown in this figure. The stirrups engaged by the fan-shaped struts are included in the vertical tie. For additional information, see Wight and Parra-Montesinos (2003). The junction of the narrow end of the fan and a CCC or CCT node may be designed using the provisions for those nodes specified herein.

normal and shear force at the interface, and the capacity of the interface shall be calculated in accordance with the interface shear resistance requirements of Articles 5.7.4.3 and 5.7.4.4.

The configuration of a truss is dependent on the geometry of the nodal regions which shall be detailed as shown in Figures 5.8.2.2-1 and 5.8.2.2-2. Proportions of nodal regions should be based on the bearing dimensions, reinforcement location, and depth of the compression zone as illustrated in Figure 5.8.2.2-1.

Figure 5.8.2.2-2—Strut-and-Tie Model for a Deep Beam

Where a strut is anchored only by reinforcement as in a CTT node, the effective concrete area of the node may be taken as shown in Figure 5.8.2.2-1c.

Figure C5.8.2.2-2—Fan-Shaped Strut Engaging Transverse Reinforcement Forming a Tie

Research has shown that a direct strut is the primary mechanism for transferring shear within a D-Region (Collins and Mitchell, 1991) (Birrcher et al., 2009) (Williams et al., 2012) (Larson et al., 2013). Therefore, a single-panel truss model is illustrated in Figure 5.8.2.2-2 and, according to these provisions, may be used in regions where the shear-span to depth ratio is less than 2 as may occur in transfer girders, bents, pile caps, or corbels. While these provisions limit the application of the STM to a ratio of 2 as the transition between B-Regions and D-Regions, research has shown that the actual transition is gradual and occurs over the range of $a/d = 2$ to $a/d = 2.5$. The distance, a , shown in Figure C5.8.2.2-2, is often referred to as the shear span.

A strut-and-tie truss model is shown in Figure C5.8.2.2-3 for a simply supported deep beam. The zones of high unidirectional compressive stress in the concrete are represented by struts. The regions of the concrete subjected to multidirectional stresses, where the struts and ties meet the joints of the truss, are represented by nodal zones.

Efficient and inefficient methods for modeling a simply supported beam are depicted in Figure C5.8.2.2-3. To satisfy the 25-degree minimum in the example shown, the least number of truss panels that can be provided between the applied loads and the supports is two, as shown on the left side of the beam. Two more vertical ties than necessary are used to model the flow of forces on the right side of the beam. On the right side, enough reinforcement must be provided to carry the forces in the three vertical ties each carrying $0.5P$. On the left side, only the reinforcement required to carry the force in one tie carrying $0.5P$ is needed. The

model used on the left side of the beam is more efficient since less reinforcement is needed and the resulting design is still safe.

Figure C5.8.2.2-3—Effect of Modeling on the Amount of Transverse Reinforcement

The division of the load, P , to the two diagonal struts shown in Figure C5.8.2.2-3 is relatively obvious due to symmetry. A more general situation is shown in Figure C5.8.2.2-4. The truss geometry is shown in Figure C5.8.2.2-4(a). A simplification in which the two struts on the right carrying forces F_1 and F_2 are resolved into F_R is shown in Figure C5.8.2.2-4(b). The same expedient is shown on the left side of the joint with the result shown in Figure C5.8.2.2-4(c). This simplification results in two CCC nodes positioned as shown in Figure C5.8.2.2-4(d). The load, P , is divided into two statically equivalent loads assumed to act in the center of the tributary areas of the load plate. The factor, α , denotes the portion of the load supported at the right reaction in the situation shown, and $(1-\alpha)$ denotes the portion of the load supported at the left reaction. The amount of the load plate assigned to each CCC node is the same proportions. Note that once the load is separated into two loads, there is an associated change in the angles defining the resolved struts indicated by the change from θ_{s2} to θ_{s3} .

Figure C5.8.2.2-4—Division of Node when Struts Enter from Both Sides

The estimated resistance at which diagonal cracks begin to form, V_{cr} , is determined for the initial geometries of the D-Regions using the following expression (Birrcher et al., 2009):

$$V_{cr} = \left[0.2 - 0.1 \left(\frac{a}{d} \right) \right] \sqrt{f'_c b_w d} \quad (\text{C5.8.2.2-1})$$

but not greater than $0.158 \sqrt{f'_c b_w d}$, nor less than $0.0632 \sqrt{f'_c b_w d}$.

where:

a = shear span (in.)

d = effective depth of the member (in.)
 f'_c = compressive strength of concrete for use in design (ksi)
 b_w = width of member's web (in.)

Where the shear in service is less than V_{crs} reasonable assurance is provided that shear cracks are unlikely to form.

Stresses in an STM concentrate at the nodal zones. Failure of the structure may be attributed to the crushing of concrete in these critical nodal regions. For this reason, the capacity of a truss model may be directly related to the geometry of the nodal regions. Since the compressive stress will be highest at a node there is no need to investigate compression elsewhere in the strut. Where the thickness of the strut varies along its length, a more refined model, such as that shown in Figure C5.8.2.2-5 for a strut through the flanges and web of an I-beam, may be necessary. As shown in the figure, the highest compressive stress in each strut will still be at a node.

Figure C5.8.2.2-5—Refined Model for Strut with Varying Thickness along Its Length

Interior nodes that are not bounded by a bearing plate are referred to as smeared nodes, an example of which is shown in Figure 5.8.2.2-1(c). A check of concrete stresses in smeared nodes is unnecessary (Schlaich et al., 1987).

A possible application of the STM to a spread footing is shown in Figure C5.8.2.2-6. In the figure, the contact pressure is shown as a uniform load. Traditionally, crack control reinforcement as specified in Article 5.8.2.6 is often omitted from footings in which case the concrete efficiency factor, v , would be limited to 0.45 by the provisions of Article 5.8.2.5.3a. This is analogous to the exemption for transverse reinforcement permitted in Article 5.7.2.3.

Figure C5.8.2.2-6—Application of the STM to a Spread Footing

A uniform load may be treated as a series of concentrated loads as shown in Figure C5.8.2.2-7 which shows treatment of mixed beam reactions and self-weight of an inverted T-cap straddle bent.

Figure C5.8.2.2-7—Application of the STM to Straddle Bent with Mixed Loads

Additional guidance on treating distributed loads and reaction fanning can be found in Mitchell and Collins (2013), Martin and Sanders (2007), and Birrcher et.al. (2009). Application of the STM to integral pier caps, albeit with different nodal design procedures, can be found in Martin and Sanders (2007).

5.8.2.3—Factored Resistance

The factored resistance, P_r , of a node face and ties shall be taken as that of axially loaded components:

$$P_r = \phi P_n \quad (5.8.2.3-1)$$

where:

- ϕ = resistance factor for tension or compression, specified in Article 5.5.4.2, as appropriate
 P_n = nominal resistance of a node face or tie (kip)

5.8.2.4—Proportioning of Ties

5.8.2.4.1—Strength of Tie

The nominal resistance of a tie in kips shall be taken as:

$$P_n = f_y A_{st} + A_{ps} [f_{pe} + f_y] \quad (5.8.2.4.1-1)$$

where:

- f_y = yield strength of nonprestressed longitudinal reinforcement (ksi)
 A_{st} = total area of longitudinal nonprestressed reinforcement (in.²)
 A_{ps} = area of prestressing steel (in.²)
 f_{pe} = effective stress in prestressing steel (ksi)

The sum of f_{pe} and f_y in Eq. 5.8.2.4.1-1 shall not be taken greater than the yield strength of the prestressing steel.

5.8.2.4.2—Anchorage of Tie

The tie reinforcement shall be anchored to transfer the tension force therein to the node regions of the truss in accordance with the requirements for development of reinforcement as specified in Articles 5.9.4.3 and 5.10.8.2.

C5.8.2.4.1

The second term of the equation for P_n is intended to ensure that the prestressing steel does not reach its yield point, thus a measure of control over unlimited cracking is maintained. It does, however, acknowledge that the stress in the prestressing elements will be increased due to the strain that will cause the concrete to crack. The increase in stress corresponding to this action is arbitrarily limited to the same increase in stress that the nonprestressed reinforcement will undergo. If there is no nonprestressed reinforcement, f_y may be taken as 60.0 ksi in the second term of Eq. 5.8.2.4.1-1.

C5.8.2.4.2

The ties must be properly anchored to ensure that the tie force can be fully developed and that the structure can achieve the resistance assumed by the STM. For a tie to be properly anchored at a nodal region, the yield resistance of the nonprestressed reinforcement should be developed at the point where the centroid of the bars exits the extended nodal zone as shown in Figure C5.8.2.4.2-1. In other words, the critical section for the development of the tie is taken at the location where the centroid of the bars intersects the edge of the diagonal strut.

Figure C5.8.2.4.2-1—Available Development Length for Ties

5.8.2.5—Proportioning of Node Regions

5.8.2.5.1—Strength of a Node Face

The nominal resistance of the node face shall be taken as:

$$P_n = f_{cu} A_{cn} \quad (5.8.2.5.1-1)$$

where:

- P_n = nominal resistance of a node face (kip)
- f_{cu} = limiting compressive stress at the node face, as specified in Article 5.8.2.5.3 (ksi)
- A_{cn} = effective cross-sectional area of the node face, as specified in Article 5.8.2.5.2 (in.²)

Where the back face of a CCC node contains nonprestressed compressive reinforcement, the resistance given by Eq. 5.8.2.5.1-1 may be augmented with the yield resistance of the nonprestressed reinforcement.

5.8.2.5.2—Effective Cross-Sectional Area of the Node Face

The value of A_{cn} shall be determined by considering the details of the nodal region and the in-plane dimensions illustrated in Figure 5.8.2.2-1. The out-of-plane dimension may be based on the bearing device or devices, or the dimension of the member, as appropriate.

When a strut is anchored by reinforcement, the height of the back face, h_a , of the CCT node may be considered to extend twice the distance from the exterior surface of the beam to the centroid of the longitudinal tensile reinforcement, as shown in Figure 5.8.2.2-1(b).

The depth of the back face of the CCC node, h_a , as shown in Figure 5.8.2.2-1(a), may be taken as the effective depth of the compression stress block determined from a conventional flexural analysis.

5.8.2.5.3—Limiting Compressive Stress at the Node Face

5.8.2.5.3a—General

Unless confinement reinforcement is provided and its effect is supported by analysis or experimentation, the limiting compressive stress at the node face, f_{cu} , shall be taken as:

$$f_{cu} = m v f'_c \quad (5.8.2.5.3a-1)$$

where:

- m = confinement modification factor, taken as $\sqrt{A_2/A_1}$ but not more than 2.0 as defined in Article 5.6.5, where:

C5.8.2.5.2

Research has shown that the shear behavior of conventionally reinforced deep beams, as wide as 36.0 in., is not significantly influenced by the distribution of stirrups across the section. Beams wider than 36.0 in., or beams with a width to height aspect ratio greater than one, may benefit from distributing the area of transverse reinforcement across the width of the cross-section. Based on limited research, the additional stirrup legs should be spaced transversely no more than the shear depth of the beam but no less than 30.0 in. (Bircher et al., 2009). The 30.0 in. recommendation is based on the spacing of the legs on the transverse in the 36.0 in. wide beams, rounded down to a convenient number.

C5.8.2.5.3a

Concrete efficiency factors have been selected based on simplicity in application, compatibility with other sections of the specifications, compatibility with tests of D-Regions, and compatibility with other provisions.

Eq. 5.8.2.5.3a-1 is valid for design concrete compressive strengths up to 15.0 ksi and therefore stress-block factors, k_c and α_1 , for high-strength concrete need not be applied to this equation.

The efficiency factors specified herein were derived for nonhydrostatic nodes and are shown graphically in Figure C5.8.2.5.3a-1.

- A_1 = area under the bearing device (in.²)
 A_2 = notional area specified in Article 5.6.5 (in.²)
 v = concrete efficiency factor:
 - 0.45 for structures that do not contain crack control reinforcement as specified in Article 5.8.2.6
 - as shown in Table 5.8.2.5.3a-1 for structures with crack control reinforcement as specified in Article 5.8.2.6 f'_c = compressive strength of concrete for use in design (ksi)

In addition to satisfying strength criteria, the node regions shall be designed to comply with the stress and anchorage limits specified in Articles 5.8.2.4.1 and 5.8.2.4.2.

Figure C5.8.2.5.3a-1—Depiction of Efficiency Factors

Table 5.8.2.5.3a-1—Efficiency Factors for Nodes with Crack Control Reinforcement

Face	Node Type		
	CCC	CCT	CTT
Bearing Face	0.85	0.70	
Back Face			
Strut-to-Node Interface	$0.85 - \frac{f'_c}{20 \text{ ksi}}$	$0.85 - \frac{f'_c}{20 \text{ ksi}}$	$0.85 - \frac{f'_c}{20 \text{ ksi}}$
	$0.45 \leq v \leq 0.65$	$0.45 \leq v \leq 0.65$	$0.45 \leq v \leq 0.65$

5.8.2.5.3b—Back Face of a CCT Node

C5.8.2.5.3b

Bond stresses resulting from the force in a developed tie as shown in Figure 5.8.2.5.3b-1 need not be applied to the back face of the CCT node.

An examination of experimental studies in the literature did not reveal any cases where the back face of a CCT node controlled the capacity in test specimens where deformed bars were used as tie steel. (Bircher et al., 2009)

Figure 5.8.2.5.3b-1—Bond Stress Resulting from the Anchorage of a Developed Tie

The bearing stresses resulting from an anchor plate or headed bar, or an external indeterminacy such as that which occurs at a node over a continuous support as shown in Figure 5.8.2.5.3b-2 shall be investigated using the applicable provisions of Article 5.8.2.5.

(a) Bearing Stress Applied from an Anchor Plate or Headed Bar

Figure 5.8.2.5.3b-2—Stress Condition at the Back Face of a CCT Node

If the stress applied to the back face of a CCT node is from an anchor plate or headed bar, a check of the back face stresses should be made assuming that the bar is unbonded and all of the tie force is transferred to the anchor plate or bar head.

If the stress applied to the back face of a CCT node is the result of a combination of both anchorage and a discrete force from another strut, it is only necessary to proportion the node to resist the direct compression stresses. It is not necessary to apply the bonding stresses to the back face, provided the tie is adequately anchored.

Where necessary, interior layers of crack control reinforcement may be used.

reinforcement provided in that specimen was less than 0.003 times the effective area of the strut.

Figure C5.8.2.6-1—Distribution of Crack Control Reinforcement in Struts

5.8.2.7—Application to the Design of the General Zones of Post-Tensioning Anchorages

5.8.2.7.1—General

The flow of forces in the anchorage zone may be approximated by a strut-and-tie model as specified herein.

All forces acting on the anchorage zone shall be considered in the selection of a strut-and-tie model which should follow a load path from the anchorages to the end of the anchorage zone.

C5.8.2.7.1

A conservative estimate of the resistance of a concrete structure or member may be obtained by application of the lower bound theorem of the theory of plasticity of structures. If sufficient ductility is present in the system, strut-and-tie models fulfill the conditions for the application of the above-mentioned theorem. Figure C5.8.2.7.1-1 shows the linear elastic stress field and a corresponding strut-and-tie model for the case of an anchorage zone with two eccentric anchors (Schlaich et al., 1987).

Because of the limited ductility of concrete, strut-and-tie models, which are not greatly different from the elastic solution in terms of stress distribution, should be selected. This procedure will reduce the required stress redistributions in the anchorage zone and ensure that reinforcement is provided where cracks are most likely to occur. Strut-and-tie models for some typical load cases for anchorage zones are shown in Figure C5.8.2.7.1-2.

Figure C5.8.2.7.1-3 shows the STM for the outer regions of general anchorage zones with eccentrically located anchorages. The anchorage local zone becomes a node for the STM and the adequacy of the node must be checked by appropriate analysis or full-scale testing.

Figure C5.8.2.7.1-1—Principal Stress Field and Superimposed STM

Figure C5.8.2.7.1-2—STMs for Selected Anchorage Zones

Figure C5.8.2.7.1-3—STM for the Outer Regions of the General Zone

5.8.2.7.2—Nodes

Local zones that satisfy the requirements of Article 5.8.4.4 of these Specifications or Article 10.3.2.3 of the *AASHTO LRFD Bridge Construction Specifications* may be considered as properly detailed and are adequate nodes. The other nodes in the anchorage zone may be considered adequate if the effective concrete stresses in the struts satisfy the requirements of Article 5.8.2.7.3, and the ties are detailed to develop the full yield strength of the reinforcement.

5.8.2.7.3—Struts

The factored compressive stress shall not exceed the limits specified in Article 5.9.5.6.5a.

In anchorage zones, the critical section for struts may normally be taken at the interface with the local zone node. If special anchorage devices are used, the critical section of the strut may be taken as the section whose extension intersects the axis of the tendon at a depth equal to the smaller of the depth of the local confinement reinforcement or the lateral dimension of the anchorage device.

For thin members, the dimension of the strut in the direction of the thickness of the member may be approximated by assuming that the thickness of the strut varies linearly from the transverse lateral dimension of the anchor at the surface of the concrete to the total thickness of the section at a depth equal to the thickness of the section.

The compression stresses should be assumed to act parallel to the axis of the strut and to be uniformly distributed over its cross-section.

C5.8.2.7.2

Nodes are critical elements of the strut-and-tie model. The entire local zone constitutes the most critical node or group of nodes for anchorage zones. In Article 5.8.4.4 of these Specifications, the adequacy of the local zone is ensured by limiting the bearing pressure under the anchorage device. Alternatively, this limitation may be exceeded if the adequacy of the anchorage device is proven by the acceptance test of Article 10.3.2.3 of the *AASHTO LRFD Bridge Construction Specifications*.

C5.8.2.7.3

For STMs oriented on the elastic stress distribution, the design concrete compressive strength specified in Article 5.9.5.6.5a is adequate. However, if the selected STM deviates considerably from the elastic stress distribution, large plastic deformations are required and the usable concrete strength should also be reduced if the concrete is cracked due to other load effects.

Ordinarily, the geometry of the local zone node and, thus, of the interface between strut and local zone, is determined by the size of the bearing plate and the selected strut-and-tie model, as indicated in Figure 5.8.2.2-1(a). Based on the acceptance test of Article 10.3.2.3 of the *AASHTO LRFD Bridge Construction Specifications*, the stresses on special anchorage devices should be investigated at a larger distance from the node, assuming that the width of the strut increases with the distance from the local zone.

5.8.2.7.4—Ties

Ties consisting of nonprestressed or prestressed reinforcement shall resist the total tensile force.

Ties shall extend beyond the nodes to develop the full-tie force at the node. The reinforcement layout should follow as closely as practical the paths of the assumed ties in the strut-and-tie model.

5.8.2.8—Application to the Design of Pier Diaphragms

The flow of forces in pier diaphragms may be approximated by the STM.

C5.8.2.7.4

Because of the unreliable strength of concrete in tension, it is prudent to neglect it entirely in resisting tensile forces.

In the selection of a strut-and-tie model, only practical reinforcement arrangements should be considered. The reinforcement layout, actually detailed on the plans, should be in agreement with the selected strut-and-tie model.

C5.8.2.8

Figure C5.8.2.8-1 illustrates the application of the STM to analysis of forces in a prestressed interior diaphragm of a box girder bridge.

Figure C5.8.2.8-1—Diaphragm of a Box Girder Bridge: (a) Disturbed Regions and Model of the Web near the Diaphragm; (b) Diaphragm and Model; (c) and (d) Prestressing of the Web and the Diaphragm (Schlaich et al., 1987)

5.8.2.9—Application to the Design of Brackets and Corbels

The flow of forces in corbels and beam ledges may be approximated by the STM as an alternative to the provisions of Article 5.8.4.2.2. Detailing shall conform to the applicable provisions of Article 5.8.4.2.

C5.8.2.9

Figure C5.8.2.9-1 illustrates the application of strut-and-tie models to analysis of brackets and corbels.

Figure C5.8.2.9-1—Different Support Conditions Leading to Different Strut-and-Tie Models and Different Reinforcement Arrangements of Corbels and Beam Ledges (Schlaich et al., 1987)

Figure C5.8.2.9-1 (continued) — Different Support Conditions Leading to Different Strut-and-Tie Models and Different Reinforcement Arrangements of Corbels and Beam Ledges (Schlaich et al., 1987)

5.8.3—Elastic Stress Analysis

5.8.3.1—General

Analyses based on elastic material properties, equilibrium of forces and loads, and compatibility of strains may be used for the analysis and design of anchorage zones.

5.8.3.2—General Zones of Post-Tensioning Anchorages

If the compressive stresses in the concrete ahead of the anchorage device are determined from an elastic analysis, local stresses may be averaged over an area equal to the bearing area of the anchorage device.

5.8.4—Approximate Stress Analysis and Design

5.8.4.1—Deep Components

Although the STM of Article 5.8.2 is the preferred method for designing deep components, legacy methods that have served an Owner well may be used provided that all of the following are met:

- The provisions of Article 5.8.2.6 specifying the amount and spacing of crack control reinforcement are met as a minimum;

C5.8.4.1

ACI 318-14 contains further information on, and references for, deep component legacy methods. No particular method is specified or recommended although crack control reinforcement and a limit on shear capacity is specified.

Many of the treatments of deep components in the literature deal with situations where the load is applied on top of the component and the support is located on

- A limit on usable shear capacity is specified;
- The loading is placed at the appropriate depth of the component relative to the reactions in a manner consistent with the legacy method being used;
- The method of analysis reflects the disturbed stress field, the behavior of cracked concrete, and other nonlinear behavior anticipated at the strength or extreme event limit states.

the bottom. Unless a legacy method expressly treats situations in which loads are applied along the web or near the bottom of the component, the behavior can be accurately accounted for only by the STM or a finite element analysis utilizing nonlinear material properties that also accounts for cracked concrete.

5.8.4.2—Brackets and Corbels

5.8.4.2.1—General

The section at the face of the support for brackets and corbels may be designed in accordance with either the STM specified in Article 5.8.2 or the alternative to strut-and-tie model specified in Article 5.8.4.2.2.

Components in which a_v , as shown in Figure 5.8.4.2.1-1, is less than d shall be considered to be brackets or corbels. If a_v is greater than d , the component shall be designed as a cantilever beam.

C5.8.4.2.1

Figure 5.8.4.2.1-1—Typical Bracket or Corbel

The section at the face of support shall be designed to resist simultaneously a factored shear force, V_u , a factored moment, M_u , and the concurrent factored tensile force, N_{uc} , where:

$$M_u = V_u a_v + N_{uc} (h - d) \quad (5.8.4.2.1-1)$$

and a concurrent factored horizontal tensile force, N_{uc} . Unless special provisions are made to prevent the tensile force, N_{uc} , from developing, it shall not be taken to be less than $0.2V_u$. N_{uc} shall be regarded as a live load, even where it results from creep, shrinkage, or temperature change.

The steel ratio of A_s/bd at the face of the support shall not be less than $0.04f'_c/f_y$, where d is measured at the face of the support.

The total area, A_h , of the closed stirrups or ties shall not be less than 50 percent of the area, A_s , of the primary tensile tie reinforcement. Stirrups or ties shall be uniformly distributed within two thirds of the effective depth adjacent to the primary tie reinforcement.

At the front face of a bracket or corbel, the primary tension reinforcement shall be anchored to develop the specified yield strength, f_y .

Anchorage for developing reinforcement may include:

- a structural weld to a transverse bar of at least equal size;
- bending the primary bars down to form a continuous loop; or
- some other positive means of anchorage.

The bearing area on a bracket or corbel shall not project either beyond the straight portion of the primary tension bars or beyond the interior face of any transverse anchor bar.

The depth at the outside edge of the bearing area shall not be less than half the depth at the face of the support.

5.8.4.2.2—Alternative to Strut-and-Tie Model

Where the provisions of Article 5.8.4.2.1 are invoked, all of the following shall apply:

- Design of shear-friction reinforcement, A_{vf} , to resist the factored shear force, V_u , shall be as specified in Article 5.7.4, except that:

For normal weight concrete, nominal shear resistance, V_n , shall be determined as the lesser of the following:

$$V_n = 0.2f'_c b d_e \quad (5.8.4.2.2-1)$$

$$V_n = 0.8 b d_e \quad (5.8.4.2.2-2)$$

For lightweight concrete, nominal shear resistance, V_n , shall be determined as the lesser of the following:

$$V_n = \left(\frac{0.2 - 0.07a_v}{d_e} \right) f'_c b d_e \quad (5.8.4.2.2-3)$$

$$V_n = \left(\frac{0.8 - 0.28a_v}{d_e} \right) b d_e \quad (5.8.4.2.2-4)$$

- Reinforcement, A_s , to resist the factored force effects shall be determined as for ordinary members subjected to flexure and axial load.

- Area of primary tension reinforcement, A_s , shall satisfy:

$$A_s \geq \frac{2A_{vf}}{3} + A_n, \text{ and} \quad (5.8.4.2.2-5)$$

- The area of closed stirrups or ties placed within a distance equal to $2d_e/3$ from the primary reinforcement shall satisfy:

$$A_h \geq 0.5(A_s - A_n) \quad (5.8.4.2.2-6)$$

in which:

$$A_n \geq \frac{N_{uc}}{\phi f_y} \quad (5.8.4.2.2-7)$$

where:

- b = width of corbel or ledge (in.)
- d_e = depth of center of gravity of steel (in.)
- A_{vf} = area of shear-friction reinforcement (in.²)
- A_n = area of reinforcement in bracket or corbel resisting tensile force N_{uc} (in.²)

5.8.4.3—Beam Ledges

5.8.4.3.1—General

As illustrated in Figure 5.8.4.3.1-1, beam ledges shall resist:

- Flexure, shear, and horizontal forces at the location of Crack 1;
- Tension force in the supporting element at the location of Crack 2;
- Punching shear at points of loading at the location of Crack 3; and
- Bearing force at the location of Crack 4.

C5.8.4.3.1

Beam ledges may be distinguished from brackets and corbels in that their width along the face of the supporting member is greater than $(W + 5a_f)$, as shown in Figure 5.8.4.3.1-1. In addition, beam ledges are supported primarily by ties to the supporting member, whereas corbels utilize a strut penetrating directly into the supporting member. Beam ledges are generally continuous between points of application of bearing forces. Daps should be considered to be inverted beam ledges.

Examples of beam ledges include hinges within spans and inverted T-beam caps, as illustrated in Figure C5.8.4.3.1-1. In the case of an inverted T-beam pier cap, the longitudinal members are supported by the flange of the T-beam acting as beam ledges.

Figure C5.8.4.3.1-1—Examples of Beam Ledges

5.8.4.3.2—Design for Shear

Design of beam ledges for shear shall be in accordance with the requirements for shear friction specified in Article 5.7.4. Nominal interface shear resistance shall satisfy Eqs. 5.8.4.2.2-1 through 5.8.4.2.2-4 wherein the width of the concrete face, b , assumed to participate in resistance to shear shall not exceed the lesser of the following:

- $(W + 4a_v)$, or $2c$, as appropriate to the situation illustrated in Figure 5.8.4.3.2-1
- S

where:

- W = width of bearing plate or pad (in.)
- c = spacing from centerline of bearing to end of beam ledge (in.)
- S = center-to-center spacing of bearings along a beam ledge (in.)

Figure 5.8.4.3.2-1—Design of Beam Ledges for Shear

5.8.4.3.3—Design for Flexure and Horizontal Force

The section at the face of support shall be designed to resist a factored horizontal force, N_u , and a factored moment, M_u , acting simultaneously, similar to that required for corbels by Eq. 5.8.4.2.1-1.

The area of total primary tension reinforcement, A_s , shall satisfy the requirements of Article 5.8.4.2.2.

The primary tension reinforcement shall be spaced uniformly within the region $(W + 5a_f)$ or $2c$, as illustrated in Figure 5.8.4.3.3-1, except that the widths of these regions shall not overlap.

Figure 5.8.4.3.3-1—Design of Beam Ledges for Flexure and Horizontal Force

5.8.4.3.4—Design for Punching Shear

C5.8.4.3.4

Notation used in this article shall be taken as shown in Figures 5.8.4.3.4-1 through 5.8.4.3.4-3.

The truncated pyramids assumed as failure surfaces for punching shear, as illustrated in Figure 5.8.4.3.4-1, shall not overlap.

To prevent overlap of failure surfaces:

- Between adjacent bearings on a beam ledge or inverted T-beam:

$$S > 2d_f + W \quad (5.8.4.3.4-1)$$

- Between bearings on opposite ledges of an inverted T-beam web:

$$b_w + 2a_v > L + 2d_f \quad (5.8.4.3.4-2)$$

where:

S = center-to-center spacing of bearing along a beam ledge (in.)

d_f = distance from top of ledge to the bottom longitudinal reinforcement (in.)

The area of concrete resisting the punching shear for each concentrated load is shown in Figure 5.8.4.3.4-1. The area of the truncated pyramid is approximated as the average of the perimeter of the bearing plate or pad and the perimeter at depth d , assuming 45-degree slopes. If the pyramids overlap, an investigation of the combined surface areas will be necessary.

W = width of bearing plate or pad (in.)
 b_w = the width of the inverted T-beam stem (in.)
 a_v = distance from face of wall to the concentrated load (in.)
 L = length of bearing pad (in.)

Nominal punching shear resistance, V_n , in kips, shall be taken as:

$$V_n = 0.125\lambda\sqrt{f'_c b_o d_f} \quad (5.8.4.3.4-3)$$

where:

λ = concrete density modification factor, as specified in Article 5.4.2.8

f'_c = compressive strength of concrete for use in design (ksi)

b_o = the perimeter of the critical section for shear enclosing the bearing pad or plate (in.)

This perimeter need not approach closer than a distance of $0.5 d_f$ to the edges of the bearing pad or plate.

For rectangular or circular pads with failure surfaces that do not overlap, b_o shall be taken as:

- At interior rectangular pads:

$$b_o = W + 2L + 2d_f \quad (5.8.4.3.4-4)$$

- At exterior rectangular pads:

$$b_o = 0.5W + L + d_f + c \leq W + 2L + 2d_f \quad (5.8.4.3.4-5)$$

- At interior circular pads:

$$b_o = \frac{\pi}{2}(D + d_f) + D \quad (5.8.4.3.4-6)$$

- At exterior circular pads:

$$b_o = \frac{\pi}{4}(D + d_f) + \frac{D}{2} + c \leq \frac{\pi}{2}(D + d_f) + D \quad (5.8.4.3.4-7)$$

where:

W = width of bearing plate or pad (in.)
 L = length of bearing pad (in.)
 c = spacing from the centerline of bearing to the end of beam ledge (in.)
 D = diameter of circular bearing pad (in.)

Figure 5.8.4.3.4-1—Failure Surfaces for Punching Shear

Figure 5.8.4.3.4-2—Critical Section for Rectangular Bearing Pads

Figure 5.8.4.3.4-3—Critical Section for Circular Bearing Pads

5.8.4.3.5—Design of Hanger Reinforcement

The hanger reinforcement specified herein shall be provided in addition to the shear reinforcement required on either side of the beam reaction being supported.

The arrangement for hanger reinforcement, A_{hr} , in single-beam ledges shall be as shown in Figure 5.8.4.3.5-1. Using the notation in Figure 5.8.4.3.5-1, the nominal shear resistance, V_n , in kips, shall be taken as:

- For the service limit state:

$$V_n = \frac{0.5 A_{hr} f_y (W + 3a_v)}{s} \quad (5.8.4.3.5-1)$$

in which $(W + 3a_v)$ shall not exceed S for interior bearing or $2c$ for exterior bearing.

- For the strength limit state:

$$V_n = \frac{A_{hr} f_y}{s} S \quad (5.8.4.3.5-2)$$

in which S shall not exceed $2c$.

where:

A_{hr} = area of one leg of hanger reinforcement as illustrated in Figure 5.8.4.3.5-1 (in.²)

S = center-to-center spacing of bearing along a beam ledge (in.)

s = spacing of hanger reinforcing bars (in.)

$$f_y = \text{specified minimum yield strength of reinforcement (ksi)}$$

a_y = distance from face of wall to the concentrated load as illustrated in Figure 5.8.4.3.5-1 (in.)

Figure 5.8.4.3.5-1—Single-Ledge Hanger Reinforcement

Using the notation in Figure 5.8.4.3.5-2, the nominal shear resistance of the ledges of inverted T-beams shall be the lesser of that specified by Eq. 5.8.4.3.5-2 and Eq. 5.8.4.3.5-3.

$$V_n = (0.063\lambda\sqrt{f'_c}b_f d_f) + \frac{A_{hr}f_y}{s}(W + 2d_f) \quad (5.8.4.3.5-3)$$

where:

b_f = the overall width of the inverted T-beam flange, as illustrated in Figure 5.8.4.3.5-2

d_f = distance from top of ledge to the bottom longitudinal reinforcement, as illustrated in Figure 5.8.4.3.5-2 (in.)

λ = concrete density modification factor, as specified in Article 5.4.2.8

Figure 5.8.4.3.5-2—Inverted T-Beam Hanger Reinforcement

Inverted T-beams shall satisfy the torsional moment provisions as specified in Articles 5.7.3.6 and 5.7.2.1.

5.8.4.3.6—Design for Bearing

For the design for bearings supported by beam ledges, the provisions of Article 5.6.5 shall apply.

5.8.4.4—Local Zones

5.8.4.4.1—Dimensions of Local Zone

Where either:

- the manufacturer has not provided edge distance recommendations; or
- edge distances have been recommended by the manufacturer, but they have not been independently verified,

then the transverse dimensions of the local zone in each direction shall be taken as the greater of:

- the corresponding bearing plate size, plus twice the minimum concrete cover required for the particular application and environment; and
- the outer dimension of any required confining reinforcement, plus the required concrete cover over the confining reinforcement for the particular application and environment.

The cover required for corrosion protection shall be as specified in Article 5.10.1.

Where the manufacturer has recommendations for minimum cover, spacing, and edge distances for a particular anchorage device, and where these dimensions have been independently verified, the transverse dimensions of the local zone in each direction shall be taken as the lesser of:

- twice the edge distance specified by the anchorage device supplier; and
- the center-to-center spacing of anchorages specified by the anchorage device supplier.

C5.8.4.4.1

The provisions of this article are to ensure adequate concrete strength in the local zone. They are not intended to be guidelines for the design of the actual anchorage hardware.

The local zone is the highly stressed region immediately surrounding the anchorage device. It is convenient to define this region geometrically, rather than by stress levels. Figure C5.8.4.4.1-1 illustrates the local zone.

Figure C5.8.4.4.1-1—Geometry of the Local Zone

Recommendations for spacing and edge distance of anchorages provided by the manufacturer shall be taken as minimum values.

The length of the local zone along the tendon axis shall not be taken less than any of the following:

- the maximum width of the local zone;
- the length of the anchorage device confining reinforcement; and
- for anchorage devices with multiple bearing surfaces, the distance from the loaded concrete surface to the bottom of each bearing surface, plus the maximum dimension of that bearing surface.

The length of the local zone shall not be taken as greater than 1.5 times the width of the local zone.

5.8.4.4.2—Bearing Resistance

Normal anchorage devices shall comply with the requirements specified herein. Special anchorage devices shall comply with the requirements specified in Article 5.8.4.4.3.

Where general zone reinforcement satisfying Article 5.9.5.6.5b is provided, and the extent of the concrete along the tendon axis ahead of the anchorage device is at least twice the length of the local zone as defined in Article 5.8.4.4.1, the factored bearing resistance of anchorages shall be taken as:

$$P_r = \phi f_n A_b \quad (5.8.4.4.2-1)$$

for which f_n is determined as the lesser of the following:

$$f_n = 0.7 f'_{ci} \sqrt{\frac{A}{A_g}} \quad (5.8.4.4.2-2)$$

$$f_n = 2.25 f'_{ci} \quad (5.8.4.4.2-3)$$

where:

- ϕ = resistance factor, specified in Article 5.5.4.2
- f_n = nominal concrete bearing stress (ksi)
- A_b = effective net area of the bearing plate calculated as the area A_g , minus the area of openings in the bearing plate (in.²)
- f'_{ci} = design concrete compressive strength at time of application of tendon force (ksi)
- A = maximum area of the portion of the supporting surface that is similar to the loaded area and concentric with it and does not overlap similar areas for adjacent anchorage devices (in.²)
- A_g = gross area of the bearing plate calculated in accordance with the requirements herein (in.²)

The full bearing plate may be used for A_g and the calculation of A_b if the plate material does not yield at the factored tendon force, taken as 1.2 times the

For closely spaced anchorages, an enlarged local zone enclosing all individual anchorages should also be considered.

C5.8.4.4.2

References to construction specifications herein and in Article C5.8.4.4.3 refer to Articles 10.3.2.3 and 10.3.2.4 of the *AASHTO LRFD Bridge Construction Specifications* and other applicable Owner contract documents.

These specifications provide bearing pressure limits for anchorage devices, called normal anchorage devices, that are not to be tested in accordance with the acceptance test of the construction specifications. Alternatively, these limits may be exceeded if an anchorage system passes the acceptance test. Figures C5.8.4.4.2-1, C5.8.4.4.2-2, and C5.8.4.4.2-3 illustrate the specifications of Article 5.8.4.4.2 (Roberts, 1990).

Figure C5.8.4.4.2-1—Area of Supporting Concrete Surface in Eq. 5.8.4.4.2-2

maximum jacking force in accordance with Article 3.4.3.2, and the slenderness of the bearing plate, n/t , shall satisfy:

$$n/t \leq 0.08 \left(\frac{E_b}{f_b} \right)^{0.33} \quad (5.8.4.4.2-4)$$

where:

- n = projection of bearing plate beyond the wedge hole or wedge plate, as appropriate (in.)
- t = average thickness of the bearing plate (in.)
- E_b = modulus of elasticity of the bearing plate material (ksi)
- f_b = the factored tendon force, divided by the effective net area of the bearing plate, A_b (ksi)

For anchorages with separate wedge plates, n may be taken as the largest distance from the outer edge of the wedge plate to the outer edge of the bearing plate. For rectangular bearing plates, this distance shall be measured parallel to the edges of the bearing plate. If the anchorage has no separate wedge plate, n may be taken as the projection beyond the outer perimeter of the group of holes in the direction under consideration.

For bearing plates that do not meet the slenderness requirement specified herein, the effective gross bearing area, A_g , shall be taken as:

- **For anchorages with separate wedge plates**—the area geometrically similar to the wedge plate, with dimensions increased by twice the bearing plate thickness.
- **For anchorages without separate wedge plates**—the area geometrically similar to the outer perimeter of the wedge holes, with dimension increased by twice the bearing plate thickness.

5.8.4.4.3—Special Anchorage Devices

Special anchorage devices that do not satisfy the requirements specified in Article 5.8.4.4.2 may be used, provided that they have been tested by an independent testing agency acceptable to the Engineer and have met the acceptance criteria specified in Articles 10.3.2 and 10.3.2.3.10 of the *AASHTO LRFD Bridge Construction Specifications*.

Figure C5.8.4.4.2—Effective Bearing Plate Area for Anchorage Devices with Separate Wedge Plate

Figure C5.8.4.4.3—Effective Bearing Plate Area for Anchorage Device without Separate Wedge Plate

A larger effective bearing area may be calculated by assuming an effective area and checking the new f_b and n/t values.

C5.8.4.4.3

Most anchorage devices fall in this category and still have to pass the acceptance test of the construction specifications. However, many of the anchorage systems currently available in the United States have passed equivalent acceptance tests. The results of these tests may be considered acceptable if the test procedure is generally similar to that specified in the construction specifications.

Local anchorage zone reinforcement supplied as part of a proprietary post-tensioning system shall be shown on post-tensioning shop drawings. Adjustment of general anchorage zone tensile reinforcement due to reinforcement supplied as part of a proprietary post-tensioning system may be considered as part of the shop drawing approval process. The responsibility for design of general anchorage zone reinforcement shall remain with the Engineer of Record.

For a series of similar special anchorage devices, tests may only be required for representative samples, unless tests for each capacity of the anchorages in the series are required by the Engineer of Record.

5.8.4.5—General Zone of Post-Tensioning Anchorages

5.8.4.5.1—Limitations of Application

Concrete compressive stresses ahead of the anchorage device, location and magnitude of the bursting force, and edge tension forces may be estimated using Eqs. 5.8.4.5.2-1 through 5.8.4.5.3-2, provided that:

- the member has a rectangular cross-section and its longitudinal extent is not less than the larger transverse dimension of the cross-section;
- the member has no discontinuities within or ahead of the anchorage zone;
- the minimum edge distance of the anchorage in the main plane of the member is not less than 1.5 times the corresponding lateral dimension, a , of the anchorage device;
- only one anchorage device or one group of closely spaced anchorage devices is located in the anchorage zone; and
- the angle of inclination of the tendon, as specified in Eqs. 5.8.4.5.3-1 and 5.8.4.5.3-2, is between -5.0 degrees and $+20.0$ degrees.

In addition to any required confining reinforcement provided in the acceptance test of special anchorage devices, supplementary skin reinforcement is permitted by the construction specifications. Equivalent reinforcement should also be placed in the actual structure. Other general zone reinforcement in the corresponding portion of the anchorage zone may be counted toward this reinforcement requirement.

C5.8.4.5.1

The equations specified herein are based on the analysis of members with rectangular cross-sections and on an anchorage zone at least as long as the largest dimension of that cross-section. For cross-sections that deviate significantly from a rectangular shape, for example I-girders with wide flanges, the approximate equations should not be used.

Discontinuities, such as web openings, disturb the flow of forces and may cause higher compressive stresses, bursting forces, or edge tension forces in the anchorage zone. Figure C5.8.4.5.1-1 compares the bursting forces for a member with a continuous rectangular cross-section and for a member with a noncontinuous rectangular cross-section. The approximate equations may be applied to standard I-girders with end blocks if the longitudinal extension of the end block is at least one girder height and if the transition from the end block to the I-section is gradual.

Anchorage devices may be treated as closely spaced if their center-to-center spacing does not exceed 1.5 times the width of the anchorage devices in the direction considered.

Figure C5.8.4.5.1-1—Effect of Discontinuity in Anchorage Zone

The approximate equations for concrete compressive stresses are based on the assumption that the anchor force spreads in all directions. The minimum edge distance requirement satisfies this assumption and is illustrated in Figure C5.8.4.5.1-2. The approximate equations for bursting forces are based on finite element analyses for a single anchor acting on a rectangular cross-section. Eq. 5.8.4.5.3-1 gives conservative results for the bursting reinforcement, even if the anchors are not closely spaced, but the resultant of the bursting force is located closer to the anchor than indicated by Eq. 5.8.4.5.3-2.

Figure C5.8.4.5.1-2—Edge Distances and Notation

5.8.4.5.2—Compressive Stresses

The concrete compressive stress ahead of the anchorage devices, f_{ca} , calculated using Eq. 5.8.4.5.2-1, shall not exceed the limit specified in Article 5.9.5.6.5a:

$$f_{ca} = \frac{0.6P_u \kappa}{A_b \left(1 + \ell_c \left(\frac{1}{b_{eff}} - \frac{1}{t} \right) \right)} \quad (5.8.4.5.2-1)$$

in which:

if $a_{eff} \leq s < 2a_{eff}$, then :

$$\kappa = 1 + \left(2 - \frac{s}{a_{eff}} \right) \left(0.3 + \frac{n}{15} \right) \quad (5.8.4.5.2-2)$$

if $s \geq 2a_{eff}$, then :

$$\kappa = 1 \quad (5.8.4.5.2-3)$$

where:

- P_u = factored tendon force (kip)
- κ = correction factor for closely spaced anchorages
- A_b = effective bearing area (in.²)
- ℓ_c = longitudinal extent of confining reinforcement of the local zone but not more than the larger of 1.15 a_{eff} or 1.15 b_{eff} (in.)
- b_{eff} = lateral dimension of the effective bearing area measured parallel to the smaller dimension of the cross-section (in.)
- t = member thickness (in.)
- a_{eff} = lateral dimension of the effective bearing area of the anchorage measured parallel to the larger dimension of the cross-section (in.)
- s = center-to-center spacing of anchorages (in.)
- n = number of anchorages in a row

The effective bearing area, A_b , in Eq. 5.8.4.5.2-1 shall be taken as the larger of the anchor bearing plate area, A_{plate} , or the bearing area of the confined concrete in the local zone, A_{conf} , with the following limitations:

C5.8.4.5.2

This check of concrete compressive stresses is not required for basic anchorage devices satisfying Article 5.8.4.4.2.

Eqs. 5.8.4.5.2-1 and 5.8.4.5.2-2 are based on a strut-and-tie model for a single anchor with the concrete stresses determined as indicated in Figure C5.8.4.5.2-1 (Burdet, 1990), with the anchor plate width, b , and member thickness, t , being equal. Eq. 5.8.4.5.2-1 was modified to include cases with values of $b < t$.

Figure C5.8.4.5.2-1—Local Zone and Strut Interface

For multiple anchorages spaced closer than $2a_{eff}$, a correction factor, κ , is necessary. This factor is based on an assumed stress distribution at a distance of one anchor plate width ahead of the anchorage device, as indicated in Figure C5.8.4.5.2-2. The definition of the effective bearing area, A_b , is shown in Figure C5.8.4.5.2-3 (Breen et al., 1994).

- If A_{plate} controls, A_{plate} shall not be taken larger than $(4/\pi) A_{conf}$.
- If A_{conf} controls, the maximum dimension of A_{conf} shall not be more than twice the maximum dimension of A_{plate} or three times the minimum dimension of A_{plate} . If any of these limits is violated, the effective bearing area, A_b , shall be based on A_{plate} .
- Deductions shall be made for the area of the duct in the determination of A_b .

If a group of anchorages is closely spaced in two directions, the product of the correction factors, κ , for each direction shall be used, as specified in Eq. 5.8.4.5.2-1.

Figure C5.8.4.5.2-2—Closely Spaced Multiple Anchorages

Figure C5.8.4.5.2-3—Effective Bearing Area

5.8.4.5.3—Bursting Forces

The bursting forces in anchorage zones, T_{burst} , may be taken as:

$$T_{burst} = 0.25 \sum P_u \left(1 - \frac{a}{h} \right) + 0.5 \left| \sum (P_u \sin \alpha) \right| \quad (5.8.4.5.3-1)$$

The location of the bursting force, d_{burst} , may be taken as:

$$d_{burst} = 0.5 (h - 2e) + 5e \sin \alpha \quad (5.8.4.5.3-2)$$

where:

- T_{burst} = tensile force in the anchorage zone acting ahead of the anchorage device and transverse to the tendon axis (kip)
- P_u = factored tendon force (kip)
- a = lateral dimension of the anchorage device or group of devices in the direction considered (in.)
- h = lateral dimension of the cross-section in the direction considered (in.)

C5.8.4.5.3

Eqs. 5.8.4.5.3-1 and 5.8.4.5.3-2 are based on the results of linear elastic stress analyses (Burdet, 1990). Figure C5.8.4.5.3-1 illustrates the terms used in the equations.

- α = angle of inclination of a tendon force with respect to the centerline of the member; positive for concentric tendons or if the anchor force points toward the centroid of the section; negative if the anchor force points away from the centroid of the section (degrees)
- d_{burst} = distance from anchorage device to the centroid of the bursting force, T_{burst} (in.)
- e = eccentricity of the anchorage device or group of devices with respect to the centroid of the cross-section; always taken as positive (in.)

The location and distribution of bursting reinforcement shall satisfy the requirements of Article 5.9.5.6.5b.

Figure C5.8.4.5.3-1—Notation for Eqs. 5.8.4.5.3-1 and 5.8.4.5.3-2

5.8.4.5.4—Edge Tension Forces

The longitudinal edge tension force may be determined from an analysis of a section located at one-half the depth of the section away from the loaded surface taken as a beam subjected to combined flexure and axial load. The spalling force may be taken as equal to the longitudinal edge tension force but not less than that specified in Article 5.9.5.6.5b.

C5.8.4.5.4

If the centroid of all tendons is located outside of the kern of the section, both spalling forces and longitudinal edge tension forces are induced. The determination of the edge tension forces for eccentric anchorages is illustrated in Figure C5.8.4.5.4-1. Either type of axial-flexural beam analysis is acceptable. As in the case for multiple anchorages, this reinforcement is essential for equilibrium of the anchorage zone. It is important to consider stressing sequences that may cause temporary eccentric loadings of the anchorage zone.

Figure C5.8.4.5.4-1—Determination of Edge Tension Forces for Eccentric Anchorages

5.8.4.5.5—Multiple Slab Anchorages

C5.8.4.5.5

Unless a more detailed analysis is made, the minimum reinforcement specified herein to resist bursting force and edge tension force shall be provided.

Reinforcement shall be provided to resist the bursting force. This reinforcement shall be anchored close to the faces of the slab with standard hooks bent

Reinforcement to resist bursting force is provided in the direction of the thickness of the slab and normal to the tendon axis in accordance with Article 5.9.5.6.5b.

around horizontal bars or equivalent. Minimum reinforcement should be two #3 bars per anchor located at a distance equal to one-half the slab thickness ahead of the anchor.

Reinforcement shall be provided to resist edge tension forces, T_1 , between anchorages and bursting forces, T_2 , ahead of the anchorages. Edge tension reinforcement shall be placed immediately ahead of the anchors and shall effectively tie adjacent anchors together. Bursting reinforcement shall be distributed over the length of the anchorage zones.

$$T_1 = 0.10 P_u \left(1 - \frac{a}{s} \right) \quad (5.8.4.5.5-1)$$

$$T_2 = 0.20 P_u \left(1 - \frac{a}{s} \right) \quad (5.8.4.5.5-2)$$

where:

- T_1 = edge tension force (kip)
- P_u = factored tendon force on an individual anchor (kip)
- a = lateral dimension of the anchorage device or group of devices in the transverse direction of the slab (in.)
- s = the anchorage spacing (in.)
- T_2 = bursting force (kip)

For slab anchors with an edge distance of less than two plate widths or one slab thickness, the edge tension reinforcement shall be proportioned to resist 25 percent of the factored tendon load. This reinforcement should be in the form of hairpins and shall be distributed within one plate width ahead of the anchor. The legs of the hairpin bars shall extend from the edge of the slab past the adjacent anchor but not less than a distance equal to five plate widths plus development length.

Reinforcement to resist edge tension force is placed in the plane of the slab and normal to the tendon axis.

The use of hairpins provides better confinement to the edge region than the use of straight bars.

5.9—PRESTRESSING

5.9.1—General Design Considerations

5.9.1.1—General

The provisions herein specified shall apply to structural concrete members reinforced with any combination of prestressing tendons and conventional reinforcing bars acting together to resist common force effects. Prestressed structural components shall be designed for both initial and final prestressing forces. They shall satisfy the requirements at service, fatigue, strength, and extreme event limit states, as specified in Article 5.5, and in accordance with the assumptions provided in Articles 5.6 and 5.7.

Unstressed prestressing tendons or reinforcing bars may be used in combination with stressed tendons, provided it is shown that performance of the structure satisfies all limit states and the requirements of Articles 5.4 and 5.5.

Compressive stress limits, specified in Article 5.9.2.3, shall be used with any applicable service load combination in Table 3.4.1-1, except Service Load Combination III, which shall not apply to the investigation of compression.

Tensile stress limits, specified in Article 5.9.2.3, shall be used with any applicable service load combination in Table 3.4.1-1. Service Load Combination III shall apply when investigating tension under live load.

5.9.1.2—Design Concrete Strengths

The design strengths, f'_c and f'_{ci} , shall be identified in the contract documents for each component. Stress limits relating to design strengths shall be as specified in Article 5.9.2.3.

Concrete strength at transfer shall be adequate for the requirements of the anchorages or for transfer through bond as well as for camber or deflection requirements.

5.9.1.3—Section Properties

For section properties prior to bonding of post-tensioning tendons, where the open ducts reduce the area of the either flange or either or both web(s) by more than 5 percent, the stresses shall be checked using section properties that account for the presence of the ducts. For both pretensioned or post-tensioned members after bonding of tendons, section properties may be based on either the gross or transformed section.

5.9.1.4—Crack Control

Where cracking is permitted under service loads, crack width, fatigue of reinforcement, and corrosion considerations shall be investigated in accordance with the provisions of Articles 5.5 and 5.6.

5.9.1.5—Buckling

Buckling of a member between points where concrete and tendons are in contact, buckling during handling and erection, and buckling of thin webs and flanges shall be investigated.

5.9.1.6—Tendons with Angle Points or Curves

The provisions of Article 5.4.6 for the curvature of ducts shall apply.

The provisions of Article 5.9.5.4 shall apply to the investigation of stress concentrations due to changes in the direction of prestressing tendons.

For tendons in draped ducts that are not nominally straight, consideration shall be given to the difference between the center of gravity of the tendon and the center of gravity of the duct when determining eccentricity.

C5.9.1.3

The 5 percent allowance reflects current common practice. Bonding means that the grout in the duct has attained its specified strength.

C5.9.1.6

Vertically draped strand tendons should be assumed to be at the bottom of the duct in negative moment areas and at the top of the duct in positive moment areas. The location of the tendon center of gravity, with respect to the centerline of the duct, is shown for negative moment in Figure C5.9.1.6-1.

The PTS Supplier should provide the eccentricity, Z , within the ducts for a given tendon size. For design purposes the values shown in Figure C5.9.1.6-1 may be used when the supplier has not yet been selected. The

The provisions of Article 5.7.1.5 for the webs of curved post-tensioned box girder bridges shall apply.

contract documents should identify whether any dimensions to the tendon shown are to the CGS or centerline of the duct.

Figure C5.9.1.6-1—Location of Tendon in Duct

5.9.2—Stress Limitations

5.9.2.1—Stresses Due to Imposed Deformation

The effects on adjoining elements of the structure of elastic and inelastic deformations due to prestressing shall be investigated. The restraining forces produced in the adjoining structural elements may be reduced due to the effects of creep.

In monolithic frames, force effects in columns and piers resulting from prestressing the superstructure may be based on the initial elastic shortening.

For conventional monolithic frames, any increase in column moments due to long-term creep shortening of the prestressed superstructure is considered to be offset by the concurrent relaxation of deformation moments in the columns due to creep in the column concrete.

The reduction of restraining forces in other members of a structure that are caused by the prestress in a member may be taken as:

- For suddenly imposed deformations:

$$F' = F(1 - e^{-\Psi(t, t_i)}); \text{ or} \quad (5.9.2.1-1)$$

- For slowly imposed deformations:

$$F' = F(1 - e^{-\Psi(t, t_i)}) / \Psi(t, t_i) \quad (5.9.2.1-2)$$

where:

- F' = reduced force effect (kip)
- F = force effect determined using the modulus of elasticity of the concrete at the time loading is applied (kip)
- e = base of natural logarithms
- $\Psi(t, t_i)$ = creep coefficient at time, t , for loading applied at time, t_i , as specified in Article 5.4.2.3.2

5.9.2.2—Stress Limitations for Prestressing Steel

The steel stress due to prestress or at the service limit state shall not exceed the lesser of the following two values:

C5.9.2.1

Additional information is contained in Leonhardt (1964).

C5.9.2.2

For post-tensioning, the short-term allowable of $0.90f_{py}$ may be allowed for short periods of time prior to seating to offset seating and friction losses,

- Specified in Table 5.9.2.2-1
- Recommended by the manufacturer of the tendons or anchorages

provided that the other values in Table 5.9.2.2-1 are not exceeded.

The steel stress at the strength and extreme event limit states shall not exceed the tensile strength limit specified in Table 5.4.4.1-1.

Table 5.9.2.2-1—Stress Limits for Prestressing Steel

Condition	Tendon Type		
	Plain High-Strength Bars	Low Relaxation Strand	Deformed High-Strength Bars
Pretensioning			
Immediately prior to transfer, f_{pbt}	$0.70f_{pu}$	$0.75f_{pu}$	—
At service limit state, f_{pe}	$0.80f_{py}$	$0.80f_{py}$	$0.80f_{py}$
Post-Tensioning			
Prior to seating—short-term f_{pbt} may be allowed	$0.90f_{py}$	$0.90f_{py}$	$0.90f_{py}$
At anchorages and couplers immediately after anchor set	$0.70f_{pu}$	$0.70f_{pu}$	$0.70f_{pu}$
Elsewhere along length of member away from anchorages and couplers immediately after anchor set	$0.70f_{pu}$	$0.74f_{pu}$	$0.70f_{pu}$
At service limit state, f_{pe}	$0.80f_{py}$	$0.80f_{py}$	$0.80f_{py}$

5.9.2.3—Stress Limits for Concrete

5.9.2.3.1—Temporary Stresses

5.9.2.3.1a—Compressive Stresses

The compressive stress limit for pretensioned and post-tensioned concrete components, including segmentally constructed bridges, shall be $0.65f'_{ci}$, except when lateral bending due to tilt, wind, or transportation induced centrifugal force are explicitly considered, the compressive stress limit at the component extremities is permitted to be increased to $0.70f'_{ci}$. These stress limits shall also apply for temporary preservice load stages, such as lifting, hauling, and erection, with concrete strength at the time of loading substituted for f'_{ci} in the stress limits.

C5.9.2.3.1a

Concrete subjected to compressive stresses at release greater than $0.70f'_{ci}$ can experience microcracking, leading to unconservative predictions of the external load to cause cracking (Birrcher and Bayrak, 2007) (Heckmann and Bayrak, 2008) (Schnittker and Bayrak, 2008) (Birrcher et al., 2010). While the coefficient 0.65 has been selected for the general case, an increase to 0.70 is permitted for peak compressive stresses, generally caused by lateral bending due to tilt or lateral loads during fabrication and construction including wind and centrifugal forces occurring during transportation of precast elements. These stresses are isolated at the extremities of the cross-section and do not represent the global stress state in the component. Figure C5.9.2.3.1a-1 illustrates the application of the compressive stress limits.

Figure C5.9.2.3.1a-1—Application of Compressive Stress Limits

5.9.2.3.1b—Tensile Stresses

The limits in Table 5.9.2.3.1b-1 shall apply for tensile stresses.

C5.9.2.3.1b

Where bonded reinforcement is provided to allow use of the increased tensile limiting stress in areas with bonded reinforcement, the tensile force must be computed. The first step in computing the tensile force, T , is to determine the depth of the tensile zone using the extreme fiber stresses at the location being considered, f_{top} and f_{bot} . The tensile stress is then integrated over the tensile zone resulting in the total tensile force. The total tensile force may be sufficiently estimated by dividing the tensile zone into smaller subzones and summing the incremental tensile force contribution of each subzone, as illustrated below. The tensile force in each subzone is the product of the subzone area and the average tensile stress acting therein. Sections with curved boundaries, such as I-beam web-flange intersections and slabs with circular voids, the subzones may be approximated with rectangular or trapezoidal shapes. The required area of reinforcement, A_s , is computed by dividing the tensile force by the permitted stress in the reinforcement.

When the depth to the neutral axis, x , is less than the depth to the reinforcement, the reinforcement is on the compression side of the uncracked cross-section and does not contribute to the tensile force, T . However, small permissible cracks will develop at the permitted stress level and reinforcement near the tension face will be engaged. For this reason, it is acceptable to assume bonded reinforcement depth equal to the concrete cover from the point of maximum tensile stress contributes to the resistance of the tensile force in the concrete.

$$T = \sum f_q A$$

$$A_s = \frac{T}{f_s}$$

where:

$f_{ci} = f_i =$ average tensile stress in the concrete of the i^{th} tensile stress subzone

A_i = area of the i^{th} tensile stress subzone

$$f_s = 0.5f_y \leq 30.0 \text{ ksi}$$

Figure C5.9.2.3.1b-1—Calculation of Tensile Force and Required Area of Reinforcement

When the depth to the neutral axis, x , is less than the depth to the reinforcement, the reinforcement is on the compression side of the uncracked cross-section and does not contribute to the tensile force, T . However, small permissible cracks will develop at the permitted stress level and reinforcement near the tension face will be engaged. For this reason, it is acceptable to assume bonded reinforcement within a depth equal to the concrete cover from the point of maximum tensile stress contributes to the resistance of the tensile force in the concrete.

Table 5.9.2.3.1b-1—Temporary Tensile Stress Limits in Prestressed Concrete

Bridge Type	Location	Stress Limit
Other Than Segmentally Constructed Bridges	In areas with bonded reinforcement (reinforcing bars or unstressed prestressing strand) sufficient to resist the tensile force in the concrete computed assuming an uncracked section, where reinforcement is proportioned using a stress of $0.5f_y$, not to exceed 30.0 ksi.	$0.24\lambda\sqrt{f'_{ci}}$ (ksi)
	In all other areas	$0.0948\lambda\sqrt{f'_{ci}} \leq 0.2$ (ksi)
	For handling stresses in prestressed piles	$0.158\lambda\sqrt{f'_{ci}}$ (ksi)
Segmentally Constructed Bridges	Longitudinal Stresses through Joints in the Precompressed Tensile Zone	
	Joints with minimum bonded auxiliary reinforcement through the joints, which is sufficient to carry the calculated tensile force at a stress of $0.5f_y$; with internal tendons or external tendons	$0.0948\lambda\sqrt{f'_{ci}}$ (ksi)
	Joints without the minimum bonded auxiliary reinforcement through the joints	No tension
	Transverse Stresses	
	For any type of joint	$0.0948\lambda\sqrt{f'_{ci}}$ (ksi)
	Stresses in Other Areas	
	- For areas without bonded nonprestressed reinforcement - In areas with bonded reinforcement (reinforcing bars or prestressing steel) sufficient to resist the tensile force in the concrete computed assuming an uncracked section, where reinforcement is proportioned using a stress of $0.5f_y$, not to exceed 30.0 ksi.	No tension $0.19\lambda\sqrt{f'_{ci}}$ (ksi)

Bonded reinforcement sufficient to resist the tensile force in the concrete shall be located as close to the tension face of the member as possible. This reinforcement must be located on the tension side of the neutral axis. When the depth to the neutral axis from the tension face of the member is less than the concrete cover as specified in Article 5.10.1, the reinforcement at a depth equal to the clear cover may be assumed to resist the tension force in the concrete for the purpose of determining the appropriate tensile stress limit in Table 5.9.2.3.1b-1.

At sections less than the development length from the end of the reinforcement, A_s shall be reduced in proportion to the lack of full development.

5.9.2.3.2—Stresses at Service Limit State

Service Limit States may be investigated assuming all time-dependent losses have occurred.

5.9.2.3.2a—Compressive Stresses

Compression shall be investigated using the Service Limit State Load Combination I specified in Table 3.4.1-1. The limits in Table 5.9.2.3.2a-1 shall apply. These limits may be used for design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi.

The reduction factor, ϕ_w , shall be taken to be equal to 1.0 when the web and flange slenderness ratios, calculated according to Article 5.6.4.7.1, are not greater than 15. When either the web or flange slenderness ratio is greater than 15, the reduction factor, ϕ_w , shall be calculated according to Article 5.6.4.7.2.

C5.9.2.3.2a

Unlike solid rectangular beams that were used in the development of concrete design codes, the unconfined concrete of the compression sides of box girders are expected to creep to failure at a stress far lower than the nominal strength of the concrete. This behavior is similar to the behavior of the concrete in thin-walled columns. The reduction factor, ϕ_w , was originally developed to account for the reduction in the usable strain of concrete in thin-walled columns at the strength limit state. The use of ϕ_w to reduce the stress limit in box girders at the service limit state is not theoretically correct. However, due to the lack of information about the behavior of the concrete at the service limit state, the use of ϕ_w provides a rational approach to account for the behavior of thin components.

The application of Article 5.6.4.7.2 to flanged, struted, and variable-thickness elements requires some judgment. Consideration of appropriate lengths of wall-type element is illustrated in Figure C5.9.2.3.2a-1. For constant thickness lengths, the wall thickness associated with that length should be used. For variable thickness lengths, e.g., L_4 , an average thickness could be used. For multilength components, such as the top flange, the highest ratio should be used. The beneficial effect of support by struts should be considered. There are no effective length factors shown. The free edge of the cantilever overhang is assumed to be supported by the parapet in Figure C5.9.2.3.2a-1.

Figure C5.9.2.3.2a-1—Suggested Choices for Wall Lengths to be Considered

Table 5.9.2.3.2a-1—Compressive Stress Limits in Prestressed Concrete at Service Limit State after Losses

Location	Stress Limit
Due to the sum of effective prestress and permanent loads	$0.45f'_c$ (ksi)
Due to the sum of effective prestress, permanent loads, and transient loads	$0.60\phi_w f'_c$ (ksi)

5.9.2.3.2b—Tensile Stresses

For longitudinal service load combinations that involve traffic loading tension stresses in members with bonded or unbonded prestressing tendons should be investigated using load combination Service III specified in Table 3.4.1-1. Load combination Service I should be investigated for load combinations that involve traffic loadings in transverse analyses of box girder bridges.

The limits in Table 5.9.2.3.2b-1 shall apply.

C5.9.2.3.2b

Severe corrosive conditions include exposure to deicing salt, water, or airborne sea salt and airborne chemicals in heavy industrial areas.

See Figure C5.9.2.3.1b-1 for calculation of required area of bonded reinforcement.

Table 5.9.2.3.2b-1—Tensile Stress Limits in Prestressed Concrete at Service Limit State

Bridge Type	Location	Stress Limit
Other Than Segmentally Constructed Bridges These limits may be used for design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi.	Tension in the Precompressed Tensile Zone, Assuming Uncracked Sections	
	For components with bonded prestressing tendons or reinforcement that are subjected to not worse than moderate corrosion conditions	$0.19\lambda\sqrt{f'_c} \leq 0.6$ (ksi)
	- For components with bonded prestressing tendons or reinforcement that are subjected to severe corrosive conditions - For components with unbonded prestressing tendons	$0.0948\lambda\sqrt{f'_c} \leq 0.3$ (ksi) No tension
Segmentally Constructed Bridges These limits may be used for design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi.	Longitudinal Stresses through Joints in the Precompressed Tensile Zone	
	- Joints with minimum bonded auxiliary reinforcement through the joints sufficient to carry the calculated longitudinal tensile force at a stress of $0.5f_y$; internal tendons or external tendons - Joints without the minimum bonded auxiliary reinforcement through joints	$0.0948\lambda\sqrt{f'_c} \leq 0.3$ (ksi) No tension
	Transverse Stresses	
	Tension in the transverse direction in precompressed tensile zone	$0.0948\lambda\sqrt{f'_c} \leq 0.3$ (ksi)
	Stresses in Other Areas	
	- For areas without bonded reinforcement - In areas with bonded reinforcement sufficient to resist the tensile force in the concrete computed assuming an uncracked section, where reinforcement is proportioned using a stress of $0.5f_y$, not to exceed 30.0 ksi	No tension $0.19\lambda\sqrt{f'_c}$ (ksi)

5.9.2.3.3—Principal Tensile Stresses in Webs

The provisions specified herein shall apply to all types of post-tensioned superstructures with internal and/or external tendons. The provisions specified herein shall also apply to pretensioned girders with a compressive strength of concrete for use in design greater than $f'_c = 10.0$ ksi. As maximum principal tensions may not occur at the neutral axis, various locations along the height of the web should be checked.

At sections where internal tendons cross near the depth at which the maximum principal tension is being checked, the provisions of Article 5.7.2.1 shall apply.

The principal tensile stresses in webs shall not exceed $0.110\lambda\sqrt{f'_c}$ when the superstructure element is subjected to the loadings of Service III limit state of Article 3.4.1, both before and after all losses and redistribution of forces.

The principal tensile stresses shall be determined using the combination of axial and shear stress which produces the greatest principal tensile stress. Vertical compressive or tensile stresses, if present, shall also be considered. Live loads for shear stress computations for I- or bulb-tee sections may be derived using the distribution factors determined from Article 4.6.2.2. Torsion need not be considered for typical I- or bulb-tee sections. For solid rectangular girders, box girders, and other hollow sections, shear stresses shall be determined using vertical shear and concurrent torsion.

Where consideration of torsion may be neglected by the provisions of Article 5.7.2 the torsional term in Eqs. 5.9.2.3.3-2 and 5.9.2.3.3-3 may be neglected.

Shear stress may be determined as:

- For open sections that may be considered thin walled such as typical I-girders and bulb-tee girders:

$$\tau = \frac{VQ_g}{I_g b_w} \quad (5.9.2.3.3-1)$$

- For stocky solid sections:

$$\tau = \frac{VQ_g}{I_g b_w} + \frac{Tp_c}{A_{cp}^2} \quad (5.9.2.3.3-2)$$

- For single cell and symmetrical two-cell hollow sections:

$$\tau = \frac{VQ_g}{I_g b_w} + \frac{T}{2A_o b_w} \quad (5.9.2.3.3-3)$$

where:

τ = shear stress in web vertical shear (ksi)
 V = shear force for Service III load combination (kip)

C5.9.2.3.3

The principal stress check is introduced to limit web cracking at the service limit state for all types of post-tensioned superstructures with internal and/or external tendons and pretensioned girders with a compressive strength of concrete for use in design greater than $f'_c = 10.0$ ksi. Experience has shown that the cracking in the webs of conventional pretensioned girders with a compressive strength of concrete for use in design up to 10.0 ksi has not been a problem and the check may be omitted.

Since this investigation is made at the service limit state Eqs. 5.9.2.3.3-2 and 5.9.2.3.3-3 for shear stress are linear combinations of the shear stresses from shear and torsion. No relief from redistribution of stresses is assumed as might be appropriate from the strength or extreme event limit states. Likewise, no adjustment for the area or perimeter of hollow sections resulting from spalling of cover has been assumed.

For precast sections made composite with a cast-in-place deck, the principal tensile stress at both the noncomposite and composite neutral axes should be checked using the shear stress and axial stress at each location.

For substructure elements, such as pier caps and straddle bents where beam theory applies, a principal tensile stress check may be made at the discretion of the designer.

Shear flow in hollow sections with more than three webs may be determined by analytic methods or finite element analysis.

For hollow sections the shear flow due to torsion is added to the shear flow from shear forces in the controlling web. The cross-hatched area enclosed by the shear flow path is defined as shown in Figure C.5.9.2.3.3-1. The individual web widths for box girders, b_w , are measured perpendicular to the web axis.

For symmetrical two-cell box girder superstructures, the area enclosed by the outer perimeter of the box girder as shown in Figure C5.9.2.3.3-1 may

- Q_g = the first moment about the neutral axis of gross concrete area above or below the height of the web where the principal tension is being checked (in.³)
- I_g = moment of inertia of the gross concrete section about the centroidal axis, neglecting the reinforcement (in.⁴)
- b_w = web width at height of the web where principal tension is being checked (in.)
- T = concurrent torsional moment for Service III load combination (kip-in.)
- p_c = length of outside perimeter of the concrete section (in.)
- A_{cp} = area enclosed by the outside perimeter of the concrete cross-section (in.²)
- B_w = total web width in single cell or symmetrical two-cell hollow sections at height of the web where principal tension is being checked (in.)
- A_o = area enclosed by shear flow path, including any area of holes therein (in.²)

Principal tensile stresses may be determined based on the analysis using Mohr's Circle, where:

$$f_{\min} = \frac{1}{2} \left((f_{pcx} + f_{pcy}) - \sqrt{(f_{pcx} - f_{pcy})^2 + (2\tau)^2} \right) \quad (5.9.2.3.3-4)$$

where:

- $f_{\min}$ = minimum principal stress in the web, tension negative (ksi)
- f_{pcx} = horizontal stress in the web (ksi)
- f_{pcy} = vertical stress in the web (ksi)

be used for the computation of A_o . For unsymmetrical two-cell box girders, or box girders with more than three webs, consideration of the interaction of the shear flow in internal webs should be included in the computing of shear stresses. For a treatment of torsion in concrete multi-cell box girder superstructures, see Chapter 7 and Appendix B of FHWA's *Post-Tensioned Box Girder Manual* (Corven, 2016).

Figure C5.9.2.3.3-1—Area Enclosed by Shear Flow Path and Web Width for Single Cell Box and Symmetrical Two-Cell Girder Superstructure

Values of $f_{\max}$ and $f_{\min}$ in Eqs. 5.9.2.3.3-4 and C5.9.2.3.3-1 are depicted in Figure C5.9.2.3.3-2.

$$f_{\max} = \frac{1}{2} \left((f_{pcx} + f_{pcy}) + \sqrt{(f_{pcx} - f_{pcy})^2 + (2\tau)^2} \right) \quad (C5.9.2.3.3-1)$$

where:

- $f_{\max}$ = maximum principal stress in the web, compression positive (ksi)

Figure C5.9.2.3.3-2—Mohr's Circle Representation of Principal Stresses

The vertical normal stress in webs is typically equal to zero. Vertical compression shown in Figure C5.9.2.3.3-2 represents the general, but less frequent, case of biaxial stress in the webs. An example of biaxial compression would be a post-tensioned concrete box girder superstructure with vertical prestressing in the webs.

The principal tension calculation methods in Article 5.9.2.3.3 reflect the standard practice of including only the shear and normal stresses in the computation of the principal stresses. While these methods do not consider the effect of flexural stresses due to transverse moments on the calculation of the principal stresses, they have been shown to be adequate for the design of well-proportioned box girder bridges in conjunction with using the principal stress limits in this specification. The Designer should be aware that flexural stresses due to transverse moments do affect principal stresses and may want to consider their inclusion in the principal stress calculation for atypically proportioned box girder bridges. The principal tensile stress limit in this specification does not strictly apply if flexural stresses are included in the principal stress computation.

5.9.3—Prestress Losses

5.9.3.1—Total Prestress Loss

Values of prestress losses specified herein shall be applicable to design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi unless stated otherwise.

In lieu of more detailed analysis, prestress losses in members constructed and prestressed in a single stage, relative to the stress immediately before transfer, may be taken as:

- In pretensioned members:

$$\Delta f_{pT} = \Delta f_{pES} + \Delta f_{pLT} \quad (5.9.3.1-1)$$

- In post-tensioned members:

$$\Delta f_{pT} = \Delta f_{pF} + \Delta f_{pA} + \Delta f_{pES} + \Delta f_{pLT} \quad (5.9.3.1-2)$$

where:

Δf_{pT}	=	total loss (ksi)
Δf_{pES}	=	sum of all losses or gains due to elastic shortening or extension at the time of application of prestress and/or external loads (ksi)
Δf_{pLT}	=	losses due to long-term shrinkage and creep of concrete, and relaxation of the steel (ksi)
Δf_{pF}	=	loss due to friction (ksi)
Δf_{pA}	=	loss due to anchorage set (ksi)

5.9.3.2—Instantaneous Losses

5.9.3.2.1—Anchorage Set

The magnitude of the anchorage set shall be the greater of that required to control the stress in the prestressing steel at transfer or that recommended by the

C5.9.3.1

Data from control tests on the materials to be used, the methods of curing, ambient service conditions, and pertinent structural details for the construction should be considered.

Accurate estimate of total prestress loss requires recognition that the time-dependent losses resulting from creep, shrinkage, and relaxation are also interdependent. However, undue refinement is seldom warranted or even possible at the design stage because many of the component factors are either unknown or beyond the control of the Designer.

Losses due to anchorage set, friction, and elastic shortening are instantaneous, whereas losses due to creep, shrinkage, and relaxation are time-dependent.

The loss across stressing hardware and anchorage devices has been measured from 2 to 6 percent (Roberts, 1993) of the force indicated by the ram pressure times the calibrated ram area. The loss varies depending on the ram and the anchor. An initial design value of three percent is recommended.

The extension of these provisions to 15.0 ksi for normal weight concrete was based on Tadros et al. (2003).

C5.9.3.2.1

Anchorage set loss is caused by the movement of the tendon prior to seating of the wedges or the anchorage gripping device. The magnitude of the

manufacturer of the anchorage. The magnitude of the set assumed for the design and used to calculate set loss shall be shown in the contract documents and verified during construction.

minimum set depends on the prestressing system used. This loss occurs prior to transfer and causes most of the difference between jacking stress and stress at transfer. A common value for anchor set is 0.375 in., although values as low as 0.0625 in. are more appropriate for some anchorage devices, such as those for bar tendons.

For wedge-type strand anchors, the set may vary between 0.125 in. and 0.375 in., depending on the type of equipment used. For short tendons, a small anchorage seating value is desirable, and equipment with power wedge seating should be used. For long tendons, the effect of anchorage set on tendon forces is insignificant, and power seating is not necessary. The 0.25-in. anchorage set value, often assumed in elongation computations, is adequate but only approximate.

Due to friction, the loss due to anchorage set may affect only part of the prestressed member.

Losses due to elastic shortening may also be calculated in accordance with Article 5.9.3.2.3 or other published guidelines (PCI, 1975) (Zia et al., 1979). Losses due to elastic shortening for external tendons may be calculated in the same manner as for internal tendons.

5.9.3.2.2—Friction

5.9.3.2.2a—Pretensioned Members

For draped prestressing tendons, losses that may occur at the hold-down devices should be considered.

5.9.3.2.2b—Post-Tensioned Members

Losses due to friction between the internal prestressing tendons and the duct wall may be taken as:

$$\Delta f_{pF} = f_{pj} (1 - e^{-(Kx + \mu \alpha)}) \quad (5.9.3.2.2b-1)$$

where:

- f_{pj} = stress in the prestressing steel at jacking (ksi)
- e = base of natural logarithms
- K = wobble friction coefficient (per ft of tendon)
- x = length of a prestressing tendon from the jacking end to any point under consideration (ft)
- μ = friction factor
- α = sum of the absolute values of angular change of prestressing steel path from jacking end, or from the nearest jacking end if tensioning is done equally at both ends, to the point under investigation (rad.)

C5.9.3.2.2b

Where large discrepancies occur between measured and calculated tendon elongations, in-place friction tests are required.

Losses due to friction between the external tendon across a single deviator pipe may be taken as:

$$\Delta f_{pF} = f_{pj} (1 - e^{-\mu(\alpha + 0.04)}) \quad (C5.9.3.2.2b-1)$$

The 0.04 radians in Eq. C5.9.3.2.2b-1 represent an inadvertent angle change. This angle change may vary depending on job-specific tolerances on deviator pipe placement and need not be applied in cases where the deviation angle is strictly controlled or precisely known, as in the case of continuous ducts passing through separate longitudinal bell-shaped holes at deviators. The inadvertent angle change need not be considered for calculation of losses due to wedge seating movement.

Values of K and μ should be based on experimental data for the materials specified and shall be shown in the contract documents. In the absence of such data, a value within the ranges of K and μ as specified in Table 5.9.3.2.2b-1 may be used.

For tendons confined to a vertical plane, α shall be taken as the sum of the absolute values of angular changes over length x .

For tendons curved in three dimensions, the total tridimensional angular change α shall be obtained by vectorially adding the total vertical angular change of the prestressing steel path from jacking end to a point under investigation, α_v , and the total horizontal angular change, α_h , of the prestressing steel path from jacking end to a point under investigation.

For slender members, the value of x may be taken as the projection of the tendon on the longitudinal axis of the member. A friction coefficient of 0.25 is appropriate for 12 strand tendons. A lower coefficient may be used for larger tendon and duct sizes. See also Article C5.12.5.3.7 for further discussion of friction and wobble coefficients.

The values of α_v and α_h may be taken as the sum of absolute values of angular changes over length, x , of the projected tendon profile in the vertical and horizontal planes, respectively.

The scalar sum of α_v and α_h may be used as a first approximation of α .

When the developed elevation and plan of the tendons are parabolic or circular, the α can be computed from:

$$\alpha = \sqrt{\alpha_v^2 + \alpha_h^2} \quad (\text{C5.9.3.2.2b-2})$$

When the developed elevation and the plan of the tendon are generalized curves, the tendon may be split into small intervals, and the above formula can be applied to each interval so that:

$$\alpha = \Sigma \Delta \alpha = \Sigma \sqrt{\Delta \alpha_v^2 + \Delta \alpha_h^2} \quad (\text{C5.9.3.2.2b-3})$$

As an approximation, the tendon may be replaced by a series of chords connecting nodal points. The angular changes, $\Delta \alpha_v$ and $\Delta \alpha_h$, of each chord may be obtained from its slope in the developed elevation and in plan.

Field tests conducted on the external tendons of a segmental viaduct in San Antonio, Texas, indicate that the loss of prestress at deviators is higher than the usual friction factor ($\mu = 0.25$) would estimate.

This additional loss appears to be due, in part, to the tolerances allowed in the placement of the deviator pipes. Small misalignments of the pipes can result in significantly increased angle changes of the tendons at the deviation points. The addition of an inadvertent angle change of 0.04 radians to the theoretical angle change accounts for this effect based on typical deviator length of 3.0 ft and placement tolerance of ± 0.375 in. The 0.04 value is to be added to the theoretical value at each deviator. The value may vary with tolerances on pipe placement.

The measurements also indicated that the friction across the deviators was higher during the stressing operations than during the seating operations.

See Podolny (1986) for a general development of friction loss theory for bridges with inclined webs and for horizontally curved bridges.

Additional friction and wobble coefficients' ranges for different types of prestressing steel and duct are provided in Table 5.1 of PTI/ASBI M50.3-19.

Table 5.9.3.2.2b-1—Friction Coefficients for Post-Tensioning Tendons

Type of Steel	Type of Duct	K	μ
Wire or strand	Rigid and semirigid galvanized metal sheathing	0.0002	0.15–0.25
	Corrugated Polymer	0.0002	0.14
	Rigid steel pipe deviators for external tendons	0	0.25
High-strength bars	Galvanized metal sheathing and Corrugated Polymer	0.0002	0.30

5.9.3.2.3—Elastic Shortening

5.9.3.2.3a—Pretensioned Members

The loss due to elastic shortening in pretensioned members shall be taken as:

$$\Delta f_{pES} = \frac{E_p}{E_{ct}} f_{cgp} \quad (5.9.3.2.3a-1)$$

where:

- E_p = modulus of elasticity of prestressing steel (ksi)
 E_{ct} = modulus of elasticity of concrete at transfer or time of load application (ksi)
 f_{cgp} = concrete stress at the center of gravity of prestressing tendons due to the prestressing force immediately after transfer and the self-weight of the member at the section of maximum moment (ksi).

The total elastic loss or gain may be taken as the sum of the effects of prestress and applied loads.

C5.9.3.2.3a

Changes in prestressing steel stress due to the elastic deformations of the section occur at all stages of loading. Historically, it has been conservative to account for this effect implicitly in the calculation of elastic shortening and creep losses considering only the prestress force present after transfer.

The change in prestressing steel stress due to the elastic deformations of the section may be determined for any load applied. The resulting change may be a loss, at transfer, or a gain, at time of superimposed load application. Where a more detailed analysis is desired, Eq. 5.9.3.2.3a-1 may be used at each section along the beam, for the various loading conditions.

In calculating f_{cgp} , using gross (or net) cross-section properties, it may be necessary to perform a separate calculation for each different elastic deformation to be included. For the combined effects of initial prestress and member weight, an initial estimate of prestress after transfer is used. The prestress may be assumed to be 90 percent of the initial prestress before transfer and the analysis iterated until acceptable accuracy is achieved. To avoid iteration altogether, Eq. C5.9.3.2.3a-1 may be used for the initial section. If the inclusion of an elastic gain due to the application of the deck weight is desired, the change in prestress force can be directly calculated. The same is true for all other elastic gains with appropriate consideration for composite sections.

When calculating concrete stresses using transformed section properties, the effects of losses and gains due to elastic deformations are implicitly accounted for, and Δf_{pES} should not be included in the prestressing force applied to the transformed section at transfer. Nevertheless, the effective prestress in the strands can be determined by subtracting losses (elastic and time-dependent) from the jacking stress. In other words, when using transformed section properties, the

prestressing strand and the concrete are treated together as a composite section in which both the concrete and the prestressing strand are equally strained in compression by a prestressing force conceived as a fictitious external load applied at the level of the strands. To determine the effective stress in the prestressing strands (neglecting time-dependent losses for simplicity) the sum of the Δf_{pES} values considered must be included. In contrast, analysis with gross (or net) section properties involves using the effective stress in the strands at any given stage of loading to determine the prestress force and resulting concrete stresses.

The loss due to elastic shortening in pretensioned members may be determined by the following alternative equation:

$$\Delta f_{pES} = \frac{A_{ps} f_{pbt} (I_g + e_m^2 A_g) - e_m M_g A_g}{A_{ps} (I_g + e_m^2 A_g) + \frac{A_g I_g E_{ci}}{E_p}} \quad (C5.9.3.2.3a-1)$$

where:

- A_{ps} = area of prestressing steel (in.²)
- f_{pbt} = stress in prestressing steel immediately prior to transfer (ksi)
- I_g = moment of inertia of the gross concrete section about the centroidal axis, neglecting the reinforcement (in.⁴)
- e_m = average prestressing steel eccentricity at midspan (in.)
- A_g = gross area of section (in.²)
- M_g = midspan moment due to member self-weight (kip-in.)
- E_{ci} = modulus of elasticity of concrete at transfer (ksi)
- E_p = modulus of elasticity of prestressing steel (ksi)

5.9.3.2.3b—Post-Tensioned Members

The loss due to elastic shortening in post-tensioned members, other than slab systems, may be taken as:

$$\Delta f_{pES} = \frac{N-1}{2N} \frac{E_p}{E_{ci}} f_{cgp} \quad (5.9.3.2.3b-1)$$

where:

- N = number of identical prestressing tendons
- f_{cgp} = sum of concrete stresses at the center of gravity of prestressing tendons due to the prestressing force after jacking and the self-weight of the member at the sections of maximum moment (ksi)

C5.9.3.2.3b

The loss due to elastic shortening in post-tensioned members, other than slab systems, may be determined by the following alternative equation:

$$\Delta f_{pES} = \frac{N-1}{2N} \frac{A_{ps} f_{pbt} (I_g + e_m^2 A_g) - e_m M_g A_g}{A_{ps} (I_g + e_m^2 A_g) + \frac{A_g I_g E_{ci}}{E_p}} \quad (C5.9.3.2.3b-1)$$

where:

- N = number of identical prestressing tendons
- A_{ps} = area of prestressing steel (in.²)
- f_{pbt} = stress in prestressing steel immediately prior to transfer as specified in Table 5.9.2.2-1 (ksi)
- I_g = moment of inertia of the gross concrete section about the centroidal axis, neglecting the reinforcement (in.⁴)

f_{cgp} values may be calculated using a steel stress reduced below the initial value by a margin dependent on elastic shortening, relaxation, and friction effects.

For post-tensioned structures with bonded tendons, f_{cgp} may be taken at the center section of the span or, for continuous construction, at the section of maximum moment.

For post-tensioned structures with unbonded tendons, the f_{cgp} value may be calculated as the stress at the center of gravity of the prestressing steel averaged along the length of the member.

For slab systems, the value of Δf_{pES} may be taken as 25 percent of that obtained from Eq. 5.9.3.2.3b-1.

e_m = average prestressing steel eccentricity at midspan (in.)

A_g = gross area of section (in.²)

M_g = midspan moment due to member self-weight (kip-in.)

E_{ci} = modulus of elasticity of concrete at transfer (ksi)

E_p = modulus of elasticity of prestressing steel (ksi)

For post-tensioned structures with bonded tendons, Δf_{pES} may be calculated at the center section of the span or, for continuous construction, at the section of maximum moment.

For post-tensioned structures with unbonded tendons, Δf_{pES} can be calculated using the eccentricity of the prestressing steel averaged along the length of the member.

For slab systems, the value of Δf_{pES} may be taken as 25 percent of that obtained from Eq. C5.9.3.2.3b-1.

For post-tensioned construction, Δf_{pES} losses can be further reduced below those implied by Eq. 5.9.3.2.3b-1 with proper tensioning procedures such as stage stressing and retensioning.

If tendons with two different numbers of strand per tendon are used, N may be determined as:

$$N = N_1 + N_2 \frac{A_{sp2}}{A_{sp1}} \quad (C5.9.3.2.3b-2)$$

where:

N_1 = number of tendons in the larger group

N_2 = number of tendons in the smaller group

A_{sp2} = cross-sectional area of a tendon in the smaller group (in.²)

A_{sp1} = cross-sectional area of a tendon in the larger group (in.²)

5.9.3.2.3c—Combined Pretensioning and Post-Tensioning

In applying the provisions of Articles 5.9.3.2.3a and 5.9.3.2.3b to components with combined pretensioning and post-tensioning, and where post-tensioning is not applied in identical increments, the effects of subsequent post-tensioning on the elastic shortening of previously stressed prestressing tendons shall be considered.

C5.9.3.2.3c

See Castrodale and White (2004) for information on computing the effect of subsequent post-tensioning on the elastic shortening of previously stressed prestressing tendons.

5.9.3.3—Approximate Estimate of Time-Dependent Losses

For standard precast, pretensioned members subject to normal loading and environmental conditions, where:

- members are made from normal weight concrete;

C5.9.3.3

The losses or gains due to elastic deformations at the time of transfer or load application should be added to the time-dependent losses to determine total losses. However, these elastic losses (or gains) must be taken equal to zero if transformed section properties are used in stress analysis.

- the concrete is either steam- or moist-cured;
- prestressing is by bars or strands with low relaxation properties; and
- average exposure conditions and temperatures characterize the site,

the long-term prestress loss, Δf_{pLT} , due to creep of concrete, shrinkage of concrete, and relaxation of steel shall be estimated using the following formula:

$$\Delta f_{pLT} = 10.0 \frac{f_{pi} A_{ps}}{A_g} \gamma_h \gamma_{st} + 12.0 \gamma_h \gamma_{st} + \Delta f_{pR} \quad (5.9.3.3-1)$$

in which:

$$\gamma_h = 1.7 - 0.01H \quad (5.9.3.3-2)$$

$$\gamma_{st} = \frac{5}{(1 + f'_{ci})} \quad (5.9.3.3-3)$$

where:

- f_{pi} = prestressing steel stress immediately prior to transfer (ksi)
- γ_h = correction factor for relative humidity of the ambient air
- γ_{st} = correction factor for specified concrete strength at time of prestress transfer to the concrete member
- Δf_{pR} = an estimate of relaxation loss taken as 2.4 ksi for low relaxation strand and in accordance with manufacturers recommendation for other types of strand (ksi)
- H = average annual ambient relative humidity (percent)

For girders other than those made with composite slabs, the time-dependent prestress losses resulting from creep and shrinkage of concrete and relaxation of steel shall be determined using the refined method of Article 5.9.3.4.

For segmental concrete bridges, lump sum losses may be used only for preliminary design purposes.

For members of unusual dimensions, level of prestressing, construction staging, or concrete constituent materials, the refined method of Article 5.9.3.4 or computer time-step methods shall be used.

5.9.3.4—Refined Estimates of Time-Dependent Losses

5.9.3.4.1—General

For nonsegmental prestressed members, more accurate values of creep-, shrinkage-, and relaxation-related losses

The approximate estimates of time-dependent prestress losses given in Eq. 5.9.3.3-1 are intended for sections with composite decks only. The losses in Eq. 5.9.3.3-1 were derived as approximations of the terms in the refined method for a wide range of standard precast prestressed concrete I-beams and inverted tee beams. The members were assumed to be fully utilized, i.e., the level of prestressing is such that concrete tensile stress at full service loads is near the maximum limit. It is further assumed in the development of the approximate method that live load moments produce about one third of the total load moments, which is reasonable for I-beam and inverted tee composite construction and conservative for noncomposite boxes and voided slabs. They were calibrated with full-scale test results and with the results of the refined method, and found to give conservative results (Al-Omaishi, 2001) (Tadros, 2003). The approximate method should not be used for members of uncommon shapes, i.e., having V/S ratios much different from 3.5 in., level of prestressing, or construction staging. The first term in Eq. 5.9.3.3-1 corresponds to creep losses, the second term to shrinkage losses, and the third to relaxation losses.

Article C5.9.3.4.2 also gives an alternative relaxation loss prediction method.

C5.9.3.4.1

See Castrodale and White (2004) for information on computing the interaction of creep effects for

than those specified in Article 5.9.3.3 may be determined in accordance with the provisions of this article. For precast pretensioned girders without a composite topping and for precast or cast-in-place nonsegmental post-tensioned girders, the provisions of Articles 5.9.3.4.4 and 5.9.3.4.5, respectively, shall be considered before applying the provisions of this Article.

For segmental construction and post-tensioned spliced precast girders, other than during preliminary design, prestress losses shall be determined by the time-step method and the provisions of Article 5.9.3, including consideration of the time-dependent construction stages and schedule shown in the contract documents. For components with combined pretensioning and post-tensioning, and where post-tensioning is applied in more than one stage, the effects of subsequent prestressing on the creep loss for previous prestressing shall be considered.

The change in prestressing steel stress due to time-dependent loss, Δf_{pLT} , shall be determined as follows:

$$\Delta f_{pLT} = (\Delta f_{pSR} + \Delta f_{pCR} + \Delta f_{pR1})_{id} + (\Delta f_{pSD} + \Delta f_{pCD} + \Delta f_{pR2} - \Delta f_{pSS})_{df} \quad (5.9.3.4.1-1)$$

where:

Δf_{pSR} = prestress loss due to shrinkage of girder concrete between transfer and deck placement (ksi)

Δf_{pCR} = prestress loss due to creep of girder concrete between transfer and deck placement (ksi)

Δf_{pR1} = prestress loss due to relaxation of prestressing strands between time of transfer and deck placement (ksi)

Δf_{pSD} = prestress loss due to shrinkage of girder concrete between time of deck placement and final time (ksi)

Δf_{pCD} = prestress loss due to creep of girder concrete between time of deck placement and final time (ksi)

Δf_{pR2} = prestress loss due to relaxation of prestressing strands in composite section between time of deck placement and final time (ksi)

Δf_{pSS} = prestress gain due to shrinkage of deck in composite section (ksi)

$(\Delta f_{pSR} + \Delta f_{pCR} + \Delta f_{pR1})_{id}$
= sum of time-dependent prestress losses between transfer and deck placement (ksi)

$(\Delta f_{pSD} + \Delta f_{pCD} + \Delta f_{pR2} - \Delta f_{pSS})_{df}$
= sum of time-dependent prestress losses after deck placement (ksi)

prestressing applied at different times.

Estimates of losses due to each time-dependent source, such as creep, shrinkage, or relaxation, can lead to a better estimate of total losses compared with the values obtained using Article 5.9.3.3. The individual losses are based on research published in Tadros et al. (2003), which aimed at extending applicability of the provisions of these Specifications to high-strength concrete.

The new approach additionally accounts for interaction between the precast and the cast-in-place concrete components of a composite member and for variability of creep and shrinkage properties of concrete by linking the loss formulas to the creep and shrinkage prediction formulas of Article 5.4.2.3.

For segmental construction, for all considerations other than preliminary design, prestress losses shall be determined as specified in Article 5.9.3, including consideration of the time-dependent construction method and schedule shown in the contract documents.

5.9.3.4.2—Losses: Time of Transfer to Time of Deck Placement

5.9.3.4.2a—Shrinkage of Girder Concrete

The prestress loss due to shrinkage of girder concrete between time of transfer and deck placement, Δf_{pSR} , shall be determined as:

$$\Delta f_{pSR} = \epsilon_{bid} E_p K_{id} \quad (5.9.3.4.2a-1)$$

in which:

$$K_{id} = \frac{1}{1 + \frac{E_p}{E_{ci}} \frac{A_{ps}}{A_g} \left(1 + \frac{A_g e_{pg}^2}{I_g} \right) [1 + 0.7 \Psi_b(t_f, t_i)]} \quad (5.9.3.4.2a-2)$$

where:

- ϵ_{bid} = concrete shrinkage strain of girder between the time of transfer and deck placement per Eq. 5.4.2.3.3-1 (in./in.)
- E_p = modulus of elasticity of prestressing steel (ksi)
- K_{id} = transformed section coefficient that accounts for time-dependent interaction between concrete and bonded steel in the section being considered for time period between transfer and deck placement
- e_{pg} = eccentricity of prestressing force with respect to centroid of girder (in.); positive in common construction where it is below girder centroid
- $\Psi_b(t_f, t_i)$ = girder creep coefficient at final time due to loading introduced at transfer per Eq. 5.4.2.3.2-1
- t_f = final maturity of concrete (day)
- t_i = age of concrete at time of transfer (day)

5.9.3.4.2b—Creep of Girder Concrete

The prestress loss due to creep of girder concrete between time of transfer and deck placement, Δf_{pCR} , shall be determined as:

$$\Delta f_{pCR} = \frac{E_p}{E_{ci}} f_{cgp} \Psi_b(t_d, t_i) K_{id} \quad (5.9.3.4.2b-1)$$

where:

$\Psi_b(t_d, t_i)$ = girder creep coefficient at time of deck placement due to loading introduced at transfer per Eq. 5.4.2.3.2-1

t_d = maturity of concrete at deck placement (day)

5.9.3.4.2c—Relaxation of Prestressing Strands

The prestress loss due to relaxation of prestressing strands between time of transfer and deck placement, Δf_{pR1} , shall be determined as:

$$\Delta f_{pR1} = \frac{f_{pt}}{K_L} \left(\frac{f_{pt}}{f_{py}} - 0.55 \right) \quad (5.9.3.4.2c-1)$$

where:

f_{pt} = stress in prestressing strands immediately after transfer, taken not less than $0.55f_{py}$ in Eq. 5.9.3.4.2c-1

K_L = factor accounting for type of steel taken as 30 for low relaxation strands and 7.0 for other prestressing steel, unless more accurate manufacturer's data are available

The relaxation loss, Δf_{pR1} , may be assumed equal to 1.2 ksi for low-relaxation strands.

C5.9.3.4.2c

Eqs. 5.9.3.4.2c-1 and 5.9.3.4.3c-1 are given for relaxation losses and are appropriate for normal temperature ranges only. Relaxation losses increase with increasing temperatures.

A more accurate equation for prediction of relaxation loss between transfer and deck placement is given in Tadros et al. (2003):

$$\Delta f_{pR1} = \left[\frac{f_{pt}}{K'_L} \frac{\log(t)}{\log(t_i)} \left(\frac{f_{pt}}{f_{py}} - 0.55 \right) \right] \left[1 - \frac{3(\Delta f_{pSR} + \Delta f_{pCR})}{f_{pt}} \right] K_{ld} \quad (C5.9.3.4.2c-1)$$

where:

t = time between strand tensioning and deck placement (day)

K'_L = factor accounting for type of steel, equal to 45 for low relaxation steel

The term in the first square brackets is the intrinsic relaxation without accounting for strand shortening due to creep and shrinkage of concrete. The second term in square brackets accounts for relaxation reduction due to creep and shrinkage of concrete. The factor K_{ld} accounts for the restraint of the concrete member caused by bonded reinforcement. It is the same factor used for the creep and shrinkage components of the prestress loss. The equation given in Article 5.9.3.4.2c is an approximation of the above formula with the following typical values assumed:

t_i = 0.75 day

t = 120 days

$$\left[1 - \frac{3(\Delta f_{pSR} + \Delta f_{pCR})}{f_{pt}} \right] = 0.67$$

K_{ld} = 0.8

5.9.3.4.3—Losses: Time of Deck Placement to Final Time

5.9.3.4.3a—Shrinkage of Girder Concrete

The prestress loss due to shrinkage of girder concrete between time of deck placement and final time, Δf_{pSD} , shall be determined as:

$$\Delta f_{pSD} = \epsilon_{shf} E_p K_{sf} \quad (5.9.3.4.3a-1)$$

in which:

$$K_{df} = \frac{1}{1 + \frac{E_p}{E_{ci}} \frac{A_{ps}}{A_c} \left(1 + \frac{A_c e_{pc}^2}{I_c} \right) [1 + 0.7 \Psi_b(t_f, t_i)]} \quad (5.9.3.4.3a-2)$$

where:

ϵ_{bdf} = shrinkage strain of girder between time of deck placement and final time per Eq. 5.4.2.3.3-1 (in./in.)

K_{df} = transformed section coefficient that accounts for time-dependent interaction between concrete and bonded steel in the section being considered for time period between deck placement and final time

A_c = area of section calculated using the gross composite concrete section properties of the girder and the deck and the deck-to-girder modular ratio (in.²)

e_{pc} = eccentricity of prestressing force with respect to centroid of composite section (in.), positive in typical construction where prestressing force is below centroid of section

I_c = moment of inertia of section calculated using the gross composite concrete section properties of the girder and the deck and the deck-to-girder modular ratio at service (in.⁴)

5.9.3.4.3b—Creep of Girder Concrete

The change in prestress (loss is positive, gain is negative) due to creep of girder concrete between time of deck placement and final time, Δf_{pCD} , shall be determined as:

$$\Delta f_{pCD} = \frac{E_p}{E_{ci}} f_{cgp} [\Psi_b(t_f, t_i) - \Psi_b(t_d, t_i)] K_{df} + \frac{E_p}{E_c} \Delta f_{cd} \Psi_b(t_f, t_d) K_{df} \quad (5.9.3.4.3b-1)$$

where:

Δf_{cd} = change in concrete stress at centroid of prestressing strands due to long-term losses between transfer and deck placement, combined with deck weight and superimposed loads (ksi)

$\Psi_b(t_f, t_d)$ = girder creep coefficient at final time due to loading at deck placement per Eq. 5.4.2.3.2-1

5.9.3.4.3c—Relaxation of Prestressing Strands

The prestress loss due to relaxation of prestressing strands in composite section between time of deck placement and final time, Δf_{pR2} , shall be determined as:

C5.9.5.4.3c

Research indicates that about one-half of the losses due to relaxation occur before deck placement; therefore, the losses after deck placement are equal to the prior losses.

$$\Delta f_{pR2} = \Delta f_{pR1} \quad (5.9.3.4.3c-1)$$

5.9.3.4.3d—Shrinkage of Deck Concrete

C5.9.3.4.3d

The prestress gain due to shrinkage of deck in composite section, Δf_{pSS} , shall be determined as:

$$\Delta f_{pSS} = \frac{E_p}{E_c} \Delta f_{cdf} K_{df} \left[1 + 0.7 \Psi_b(t_f, t_d) \right] \quad (5.9.3.4.3d-1)$$

For the typical condition where the center of gravity of the prestressing force is below the NA, deck shrinkage increases the prestressing force and is considered a “gain”, hence the negative value of Δf_{pSS} calculated from Eq. 5.9.3.4.3d-1 is substituted into Eq. 5.9.3.4.1-1 as a positive value.

in which:

$$\Delta f_{cdf} = \frac{\epsilon_{ddf} A_d E_{c \text{ deck}}}{\left[1 + 0.7 \Psi_d(t_f, t_d) \right]} \left(\frac{1}{A_c} - \frac{e_{pc} e_d}{I_c} \right) \quad (5.9.3.4.3d-2)$$

where:

- Δf_{cdf} = change in concrete stress at centroid of prestressing strands due to shrinkage of deck concrete (ksi)
- ϵ_{ddf} = shrinkage strain of deck concrete between placement and final time per Eq. 5.4.2.3.3-1 (in./in.)
- A_d = area of deck concrete (in.²)
- $E_{c \text{ deck}}$ = modulus of elasticity of deck concrete (ksi)
- $\Psi_b(t_f, t_d)$ = girder creep coefficient at final time due to loading at deck placement per Eq. 5.4.2.3.2-1
- $\Psi_d(t_f, t_d)$ = creep coefficient of deck concrete at final time due to loading introduced shortly after deck placement (overlays, barriers, etc.) per Eq. 5.4.2.3.2-1
- e_d = eccentricity of deck with respect to the gross composite section, positive in typical construction where deck is above girder (in.)

5.9.3.4.4—Precast Pretensioned Girders without Composite Topping

The equations in Article 5.9.3.4.2 and Article 5.9.3.4.3 are applicable to girders with noncomposite deck or topping, or with no topping. The values for time of deck placement in Article 5.9.3.4.2 may be taken as values at time of noncomposite deck placement or values at time of installation of precast members without topping. Time of deck placement in Article 5.9.3.4.3 may be taken as time of noncomposite deck placement or values at time of installation of precast members without topping. Area of deck for these applications shall be taken as zero.

5.9.3.4.5—Post-Tensioned Nonsegmental Girders

Long-term prestress losses for post-tensioned members after tendons have been grouted may be calculated using the provisions of Articles 5.9.3.4.1 through 5.9.3.4.4. In Eq. 5.9.3.4.1-1, the value of the term $(\Delta f_{pSR} + \Delta f_{pCR} + \Delta f_{pR1})_{id}$ shall be taken as zero.

5.9.3.5—Losses in Multi-Stage Prestressing

For staged construction or multi-stage prestressing and bridges where more exact evaluation of prestress losses is desired, calculations for loss of prestress should be made in accordance with a time-step method supported by evaluating losses incrementally for each stage of construction.

5.9.3.6—Losses for Deflection Calculations

For camber and deflection calculations of prestressed nonsegmental members made of normal weight concrete with a strength in excess of 3.5 ksi at the time of prestress, f_{cgp} and Δf_{cdp} may be computed as the stress at the center of gravity of prestressing steel averaged along the length of the member.

5.9.4—Details for Pretensioning

5.9.4.1—Minimum Spacing of Pretensioning Strand

The distance between pretensioning strands, including debonded ones, at each end of a member within the transfer length, as specified in Article 5.9.4.3.1, shall not be less than a clear distance taken as 1.33 times the maximum size of the aggregate nor less than the center-to-center distances specified in Table 5.9.4.1-1.

C5.9.3.5

See references cited in Article C5.4.2.3.2.

Staged construction refers to any bridge whose structural static scheme undergoes changes before reaching construction completion. An example would be segmental balanced cantilever construction where adjacent cantilevers are joined to make a new, continuous structure. Staged construction can also refer to changes in the cross-section of superstructure members through composite action, where prestressing is stressed both on the noncomposite and then composite cross-sections. An example would be spliced girder construction, with prestressing stressed in a first stage to make the girders continuous, and then in a second stage after the casting of the deck slab.

C5.9.4.1

The requirement to maintain the clear spacing within the transfer zone is to ensure the strands are separated sufficiently to properly transfer their prestressing force to the surrounding concrete and to reduce the stress concentration around the strands at the ends of pretensioned components at release.

Table 5.9.4.1-1—Center-to-Center Spacings for Grade 270 Strand

Strand Size (in.)	Spacing (in.)
0.7 0.62 0.6 0.5625 Special 0.5625	2.00
0.5000 0.4375 0.50 Special	1.75
0.3750	1.50

If justified by performance tests of full-scale prototypes of the design, the clear distance between strands at the end of a member may be decreased.

The minimum clear distance between groups of bundled strands shall not be less than the greater of the following:

- 1.33 times the maximum size of the aggregate
- 1.0 in.

Pretensioning strands in a member may be bundled to touch one another in an essentially vertical plane at and between hold-down locations. Strands bundled in any manner, other than a vertical plane, shall be limited to four strands per bundle.

5.9.4.2—Maximum Spacing of Pretensioning Strand in Slabs

Pretensioning strands for precast slabs shall be spaced symmetrically and uniformly and shall not be farther apart than the lesser of the following:

- 1.5 times the total composite slab thickness; or
- 18.0 in.

5.9.4.3—Development of Pretensioning Strand

5.9.4.3.1—General

In determining the resistance of pretensioned concrete components in their end zones, the gradual buildup of the strand force in the transfer and development lengths shall be taken into account.

The stress in the prestressing steel may be assumed to vary linearly from 0.0 at the point where bonding

Some Owners limit the clear distance between pretensioning strands to not less than twice the nominal size of aggregate to facilitate placing and compaction of concrete.

C5.9.4.3.1

Between the end of the transfer length and development length, the strand stress grows from the effective stress in the prestressing steel to the stress in the strand at nominal resistance of the member.

The extension of the transfer and development length provisions to normal weight concrete with design concrete compressive strengths up to 10.0 and 15.0 ksi for f'_{ci} and f'_c , respectively, is based on the work presented in NCHRP Report 603 (Ramirez and Russell, 2008).

commences to the effective stress, f_{pe} , at the end of the transfer length.

Between the end of the transfer length and the development length, the strand stress may be assumed to increase linearly, reaching the stress at nominal resistance, f_{ps} , at the development length.

For the purpose of this article, the transfer length may be taken as 60 strand diameters and the development length shall be taken as specified in Article 5.9.4.3.2.

The effects of debonding shall be considered as specified in Article 5.9.4.3.3.

The provisions of Article 5.9.4.3 may be used for design concrete compressive strengths specified in Article 5.1, including normal weight concrete with design concrete compressive strengths up to 10.0 ksi at transfer (f'_{ci}) and up to 15.0 ksi for design (f'_c).

5.9.4.3.2—Bonded Strand

Pretensioning strand shall be bonded beyond the section required to develop f_{ps} for a development length, ℓ_d , in in., where ℓ_d shall satisfy:

$$\ell_d \geq \kappa \left(f_{ps} - \frac{2}{3} f_{pe} \right) d_b \quad (5.9.4.3.2-1)$$

where:

- κ = 1.0 for pretensioned panels, piling, and other pretensioned members with a depth of less than or equal to 24.0 in.
- κ = 1.6 for pretensioned members with a depth greater than 24.0 in.
- f_{ps} = average stress in prestressing steel at the time for which the nominal resistance of the member is required (ksi)
- f_{pe} = effective stress in the prestressing steel (ksi)
- d_b = nominal strand diameter (in.)

The variation of design stress in the pretensioned strand from the free end of the strand may be calculated as follows:

- From the point where bonding commences to the end of transfer length:

$$f_{px} = \frac{f_{pe} \ell_{px}}{60 d_b} \quad (5.9.4.3.2-2)$$

- From the end of the transfer length and to the end of the development of the strand:

$$f_{px} = f_{pe} + \frac{\ell_{px} - 60 d_b}{(\ell_d - 60 d_b)} (f_{ps} - f_{pe}) \quad (5.9.4.3.2-3)$$

where:

C5.9.4.3.2

An October 1988 FHWA memorandum mandated a 1.6 multiplier on Eq. 5.9.4.3.2-1 in these Specifications. The corrected equation is conservative in nature, but accurately reflects the worst-case characteristics of strands shipped prior to 1997. To eliminate the need for this multiplier, Eq. 5.9.4.3.2-1 has been modified by the addition of the κ factor.

The correlation between steel stress and the distance over which the strand is bonded to the concrete can be idealized by the relationship shown in Figure C5.9.4.3.2-1. This idealized variation of strand stress may be used for analyzing sections within the transfer and development length at the end of pretensioned members.

- f_{px} = design stress in pretensioned strand at nominal flexural strength at section of member under consideration (ksi)
- ℓ_{px} = distance from free end of pretensioned strand to section of member under consideration (in.)

Figure C5.9.4.3.2-1—Idealized Relationship between Steel Stress and Distance from the Free End of Strand

5.9.4.3.3—Debonded Strands

C5.9.4.3.3

Straight pretensioned strands may be debonded at the ends of beams subject to the following restrictions:

- The number of strands debonded per row shall not exceed 45 percent of the strands provided in that row, unless otherwise approved by the Owner.
- Debonding shall not be terminated for more than six strands in any given section or four strands for girders using 0.7-in. diameter strand. When a total of ten or fewer strands are debonded, debonding shall not be terminated for more than four strands in any given section.
- Longitudinal spacing of debonding termination locations shall be at least $60d_b$ apart.
- Debonded strands shall be symmetrically distributed about the vertical centerline of the cross-section of the member. Debonding shall be terminated symmetrically at the same longitudinal location.

Tests completed by the Florida Department of Transportation (Shahawy, Robinson, and Batchelor, 1993) (Shahawy and Batchelor, 1991) and others (Hamilton et al., 2013) (Langefeld and Bayrak, 2012) (Shahrooz et al., 2017) indicate that the anchored strength of the strands is one of the primary contributors to the shear resistance of prestressed concrete beams in their end zones. Thus, it is critical that the provisions of Article 5.7.3.5 are met. Shahrooz et al. (2017) and others show that debonding more than the previous 25 percent limit can be achieved provided the requirement for longitudinal reinforcement (see Article 5.7.3.5) is satisfied. Shahrooz et al. (2017) test a limited number of full-scale specimens with debonding limits up to 60 percent overall and 80 percent per row with satisfactory results. The recommended limit of 45 percent per row was chosen based on concern over long-term behavior of higher debonding percentages as well as detailing practicality used by several states.

When using debonded strands, the shear resistance in the region of debonding should be thoroughly investigated with due regard to the reduction in

- E. Alternate bonded and debonded strand locations both horizontally and vertically.
- F. Where a portion or portions of a pretensioning strand are debonded and where service tension exists in the precompressed tensile zone, the development lengths, measured from the end of the debonded zone, shall be determined using Eq. 5.9.4.3.2-1 with a value of $\kappa = 2.0$.
- G. For simple span precast, pretensioned girders, debonding length from the beam end should be limited to 20 percent of the span length or one half the span length minus the development length, whichever is less.
- H. For simple span precast girders made continuous using positive moment connections, the interaction between debonding and restraint moments from time-dependent effects (such as creep, shrinkage and temperature variations) shall be considered. For additional guidance, refer to Article 5.12.3.3.
- I. For single-web flanged sections (I-beams, bulb-tees, and inverted-tees):
 - Bond all strands within the horizontal limits of the web when the total number of debonded strands exceeds 25 percent.
 - Bond all strands within the horizontal limits of the web when the bottom flange to web width ratio, b_f/b_w , exceeds 4.
 - Bond the outer-most strands in all rows located within the full-width section of the flange.
 - Position debonded strands furthest from the vertical centerline.
- J. For multi-web sections having bottom flanges (voided slab, box beams and U-beams):
 - Uniformly distribute debonded strands between webs.
 - Strands shall be bonded within 1.0 times the web width projection.
 - Bond the outer-most strands within the section.
- K. For all other sections:
 - Debond uniformly across the width of the section.
 - Bond the outer-most strands located within the section, stem, or web.

horizontal force available when considering the free body diagram in Figure C5.7.3.5-1 and to all other determinations of shear capacity provisions of this section (Articles 5.7, 5.8, and 5.9.2.3).

Russell and Burns (1994) and Russell et al. (1994) recommend that the debonded strand transfer length region should not be located within the flexural cracking region to prevent reduced flexural strength performance. The research suggests that the debonding length from the beam end be limited to 15 percent of the span length. However, past practice of exceeding the 15 percent debonding length shows that limiting the debonding length from the beam end to 20 percent of the span length is sufficient in providing adequate flexural performance. The research also suggests staggering the termination location of the debonded strands to improve the bond performance.

For sections other than single-web flanged sections, the bearing conditions could be different for each end of the section, therefore adjusting the debonding detailing based on the bearing location is impractical. Shahrooz et al. (2017) provide recommendations when the same bearing conditions exist at each end of the section.

The detailing requirements are illustrated in Figures C5.9.4.3.3-1 and C5.9.4.3.3-2. Bonding the outer-most strands is necessary to minimize cracking near the surface due to the Hoyer effect and tying of mild reinforcement to the debonding material is not desirable.

Figure C5.9.4.3.3-1—Details for Single-Web Flanged Sections

Figure C5.9.4.3.3-2—Details for Multi-Web Sections

5.9.4.4—Pretensioned Anchorage Zones

5.9.4.4.1—Splitting Resistance

The factored splitting resistance of pretensioned anchorage zones provided by reinforcement in the ends of pretensioned beams shall be taken as:

$$P_r = f_s A_s \quad (5.9.4.4.1-1)$$

where:

- f_s = stress in steel not to exceed 20.0 ksi
- A_s = total area of reinforcement located within the distance $h/4$ from the end of the beam (in.²)
- h = overall dimension of precast member in the direction in which splitting resistance is being evaluated (in.)

For pretensioned I-girders or bulb tees, A_s shall be taken as the total area of the vertical reinforcement located within a distance of $h/4$ from the end of the member, where h is the overall height of the member (in.).

For pretensioned solid or voided slabs, A_s shall be taken as the total area of the horizontal reinforcement located within a distance of $h/4$ from the end of the member, where h is the overall width of the member (in.).

For pretensioned box or tub girders, A_s shall be taken as the total area of vertical reinforcement or horizontal reinforcement located within a distance $h/4$ from the end of the member, where h is the lesser of the overall width or height of the member (in.).

For pretensioned members with multiple stems A_s shall be taken as the total area of vertical reinforcement, divided evenly among the webs, and located within a distance $h/4$ from the end of each web.

The resistance shall not be less than 4 percent of the total prestressing force at transfer.

The reinforcement shall be as close to the end of the beam as practicable.

Reinforcement used to satisfy this requirement can also be used to satisfy other design requirements.

C5.9.4.4.1

The primary purpose of the choice of the 20-ksi steel stress limit for this provision is crack control.

Splitting resistance is of prime importance in relatively thin portions of pretensioned members that are tall or wide, such as the webs of I-girders and the webs and flanges of box and tub girders. Prestressing steel that is well distributed in such portions will reduce the splitting forces, while steel that is banded or concentrated at both ends of a member will require increased splitting resistance.

For pretensioned slab members, the width of the member is greater than the depth. A tensile zone is then formed in the horizontal direction perpendicular to the centerline member.

For tub and box girders, prestressing strands are located in both the bottom flange and webs. Tensile zones are then formed in both the vertical and horizontal directions in the webs and flanges. Reinforcement is required in both directions to resist the splitting forces.

Experience has shown that the provisions of this article generally control cracking in the end regions of pretensioned members satisfactorily; however, more reinforcement than required by this article may be necessary under certain conditions. Figures C5.9.4.4.1-1 and C5.9.4.4.1-2 show examples of splitting reinforcement for tub girders and voided slabs.

Figure C5.9.4.4.1-1—Precast Trapezoidal Tub Girder

Figure C5.9.4.4.1-2—Precast Voids Slab

5.9.4.4.2—Confinement Reinforcement

For the distance of $1.5d$ from the end of the beams other than box beams, reinforcement shall be placed to confine the prestressing steel in the bottom flange. The reinforcement shall not be less than #3 deformed bars, with spacing not exceeding 6.0 in. and shaped to enclose the strands.

For box beams, transverse reinforcement shall be provided and anchored by extending the leg of stirrup into the web of the girder.

5.9.4.4.3—Horizontal Transverse Tension Tie Reinforcement

Horizontal transverse reinforcement provided to satisfy Articles 5.9.4.4.1 and 5.9.4.4.2 may also be used to satisfy this Article.

Steel bearing plate with embedded shear studs at the girder ends may be used in lieu of the requirements of this Article. Articles 5.9.4.4.1 and 5.9.4.4.2 shall still be applicable when a steel bearing plate is used.

For all single-web beam sections with a bottom flange, horizontal transverse tension tie reinforcement shall be provided to resist potential longitudinal splitting cracks in the bottom flange. The strut-and-tie model and the associated Equation 5.9.4.4.3-1 shall be used to determine the required amount of horizontal transverse tie reinforcement.

The horizontal transverse tie reinforcement shall be uniformly distributed above the bearing from the end of the girder to a point $h/4$ beyond the bearing.

The horizontal transverse tie reinforcement shall be greater than:

$$A_s f_y = \left(\frac{n_f}{N_w} \right) \left[\frac{x_p}{h_b - y_p} + \frac{x_p - c_b}{y_p} \right] \left(\frac{V_u}{\phi} \right) \quad (5.9.4.4.3-1)$$

where:

- A_s = area of tie reinforcement (in.²)
- h_b = width of bearing (in.)
- c_b = distance from the bearing reaction force on either side of the girder to the girder centerline (in.)

C5.9.4.4.2

Several Owners have elected to provide #3 deformed bars beyond the end region due to past detailing practices and better performance of the girder if impacted by an over height vehicle. The spacing varies by state, with 6-inch to 18-inch spacings being commonly noted. Shahrooz et al. (2022) also note better performance and ductility of girders with debonded strands if confinement reinforcement is extended to a location $1.5d$ past the end of the last debonded strands. Note the research showed the predicted girder ultimate capacity was achieved without the confinement steel.

C5.9.4.4.3

Figure C5.9.4.4.3-1—Strut-and-Tie Model for Confinement

Tension forces, oriented transversely across the bottom bulb of single-web flanged sections, develop requiring tie reinforcement across the bottom flange to control longitudinal cracking at the Strength I limit state. The outcome of exceeding this limit, however, is related to transverse deformation and cracking of the flange and is likely to be a serviceability issue and not catastrophic in nature. Minimum confinement reinforcement satisfying Article 5.9.4.4.2 contributes to the tie capacity, and in many instances will be sufficient to fully resist the horizontal transverse tie force calculated using Article 5.9.4.4.3. The horizontal portion of splitting reinforcement required by Article 5.9.4.4.1, if present, contributes to the tie capacity force calculated using Article 5.9.4.4.3. This approach is consistent with load transfer mechanism in Figure C5.8.2.2-5.

- $= (b_b/2)(1 - n_f/N_w)$
- f_y = yield strength of tie reinforcement (ksi)
- h_b = depth of bottom bulb (in.)
- N_w = total number of bonded strands at section
- n_f = number of bonded strands in one side of outer portion of web
- V_u = maximum factored reaction at bearing (k)
- x_p = horizontal distance from girder centerline to centroid of bonded strands in outer portion of bulb (in.)
- y_p = vertical distance from girder soffit to centroid of bonded strands in outer portion of the bulb (in.)
- ϕ = 0.9 (resistance factor for tension in strut-and-tie models)

5.9.4.5—Temporary Strands

Temporary top strands may be used to control tensile stresses in precast prestressed girders during handling and transportation. These strands may be pretensioned or post-tensioned prior to lifting the girder from the casting bed or post-tensioned prior to transportation of the girder. Detensioning of temporary strands shall be shown in the construction sequence and typically occurs after the girders are securely braced and before construction of intermediate concrete diaphragms, if applicable.

Pretensioned temporary strands are debonded over the center portion of the girder. If pretensioned, the development length, measured from the end of the debonded zone, shall be determined as described in Article 5.9.4.3.3. No other provisions of Article 5.9.4.3.3 apply to temporary strands.

Debonded temporary strands shall be symmetrically distributed about the centerline of the member.

Debonded lengths of pairs of temporary strands that are symmetrically positioned about the centerline of the member shall be equal.

The effects of temporary strands must be considered when calculating camber and loss of prestress.

In some instances, these requirements may result in impractical horizontal transverse tie reinforcement details. An embedded bearing plate would likely be practical mitigation in such cases. Research recommends limiting the resistance of the bearing plate to 50 percent of the expected demand.

C5.9.4.5

The stability of slender precast concrete girders is improved when lifting and transportation support points are moved away from the ends of the girder. The consequence of having a shorter span between support points is reduced dead load stresses to balance the stresses due to pretensioning and thus excessive tensile stresses in the top flange and compressive stresses in the bottom flange may develop. Temporary strands placed in the top flange of the girder reduce stresses and reduce the required concrete compressive strength at prestress transfer. Temporary strands in the top flange balance a portion of the primary prestressing and reduce camber and camber growth due to creep.

Temporary top strands reduce the effectiveness of the permanent prestressing. Therefore, detensioning of the temporary top strands is typically recommended. Access to pretensioned temporary top strands is typically provided through pockets in the top surface of the top flange. Detensioning must occur before the temporary strands become inaccessible. Casting deck concrete and installation of precast deck panels will typically cover temporary top strand access points in the top flange.

Detensioning of the temporary top strands results in an upward deflection of the girder. Typically, temporary top strands are detensioned one girder at a time. This results in a differential deflection between adjacent girders that can crack intermediate concrete diaphragms, if present. To mitigate this issue, temporary strands should be detensioned after the girders are securely braced, but before intermediate concrete diaphragms are placed.

Sleeves used for debonding should be of sufficient inside diameter to mitigate binding of the strand during detensioning. Experience has shown that sleeves with inside diameter 0.18 in. to 0.25 in. larger than the strand diameter provide sufficient annular space. Access pockets should be protected to prevent water intrusion into the sleeves. Water in the sleeves can freeze and result in longitudinal cracking in the top flange that

mirrors the location of the sleeves. Access pockets should be immediately patched and sealed after detensioning.

5.9.5—Details for Post-Tensioning

5.9.5.1—Minimum Spacing of Post-Tensioning Tendons and Ducts

5.9.5.1.1—Post-Tensioning Ducts—Girders Straight in Plane

Unless otherwise specified herein, the clear distance between straight post-tensioning ducts shall not be less than the greater of the following:

- 1.33 times the maximum size of the coarse aggregate; or
- 1.5 in.

Ducts may be bundled together in groups not exceeding three, provided that the spacing, as specified between individual ducts, is maintained between each duct in the zone within 3.0 ft of anchorages.

For groups of bundled ducts in construction other than segmental, the minimum clear horizontal distance between adjacent bundles shall not be less than 4.0 in. When groups of ducts are located in two or more horizontal planes, a bundle shall contain no more than two ducts in the same horizontal plane.

The minimum vertical clear distance between bundles shall not be less than the greater of the following:

- 1.33 times the maximum size of the coarse aggregate; or
- 1.5 in.

For precast construction, the minimum clear horizontal distance between groups of ducts may be reduced to 3.0 in.

For precast segmental construction where post-tensioning tendons extend through a segment joint the clear spacing between post-tensioning ducts shall not be less than the greater of the following:

- The duct internal diameter; or
- 4.0 in.

5.9.5.1.2—Post-Tensioning Ducts—Girders Curved in Plan

The minimum clear distance between curved ducts shall be as required for tendon confinement as specified in Article 5.9.5.4.3. The spacing for curved ducts shall not be less than that required for straight ducts.

Figure C5.9.5.4.1-1—Reinforcement for Ducts in the Bottom Flanges of Variable Depth Segments

5.9.5.4.2—Wobble Effect in Slabs

For the purpose of this Article, ducts spaced closer than 12.0 in. center-to-center in either direction shall be considered as closely spaced.

Where closely spaced transverse or longitudinal ducts are located in the flanges, and no provisions to minimize wobble of ducts are included in the contract documents, the top and bottom reinforcement mats should be tied together with #4 hairpin bars. The spacing between the hairpin bars shall not exceed the lesser of the following in each direction:

- 18.0 in.; or
- 1.5 times the slab thickness.

5.9.5.4.3—Effects of Curved Tendons

Reinforcement shall be used to confine curved tendons if required by Article 5.7.1.5. The reinforcement shall be proportioned to ensure that the steel stress at service limit state does not exceed $0.6f_y$, and the assumed value of f_y shall not exceed 60.0 ksi. Unless a strut-and-tie analysis is done and indicates otherwise, spacing of the confinement reinforcement shall not exceed the lesser of the following:

- 3.0 times the outside diameter of the duct; or

C5.9.5.4.2

The hairpin bars are provided to prevent slab delamination along the plane of the post-tensioning ducts.

C5.9.5.4.3

Curved tendons induce deviation forces that are radial to the tendon in the plane of tendon curvature. Curved tendons with multiple strands or wires also induce out-of-plane forces that are perpendicular to the plane of tendon curvature.

In-plane force effects are due to a change in direction of the tendon within the plane of curvature. Resistance to in-plane forces in curved girders may be provided by increasing the concrete cover over the duct, by adding confinement tie reinforcement, or by a combination thereof. Figure C5.9.5.4.4a-1 shows an in-

- 24.0 in.

Tendons shall not be bundled in groups greater than three when girders are curved in horizontal plane.

5.9.5.4.4—Design for In-Plane Force Effects

5.9.5.4.4a—In-Plane Force Effects

In-plane deviation force effects due to the change in direction of tendons shall be taken as:

$$F_{u-in} = \frac{P_u}{R} \quad (5.9.5.4.4a-1)$$

where:

- F_{u-in} = in-plane deviation force effect per unit length of tendon (kips/ft)
 P_u = factored tendon force, as specified in Article 3.4.3 (kip)
 R = radius of curvature of the tendon at the considered location (ft)

The maximum deviation force shall be determined on the basis that all the tendons, including provisional tendons, are stressed. The provisions of Article 5.9.5.6 shall apply to design for in-plane force effects due to tendons curved at the tendon anchorage.

plane deviation in the vertical curve and Figure C5.9.5.4.4a-2 shows a potential in-plane deviation in the horizontal curve.

Out-of-plane force effects are due to the spreading of the wires or strands within the duct. Out-of-plane force effects are shown in Figure C5.9.5.4.5-1 and can be affected by ducts stacked vertically or stacked with a horizontal offset.

C5.9.5.4.4a

In-plane forces occur, for example, in anchorage blisters or curved webs, as shown in Figures C5.9.5.4.4a-1 and C5.9.5.4.4a-2. Without adequate reinforcement, the tendon deviation forces may rip through the concrete cover on the inside of the tendon curve, or unbalanced compressive forces may push off the concrete on the outside of the curve. Small radial tensile stresses may be resisted by concrete in tension.

The load factor of 1.2 taken from Article 3.4.3 and applied to the maximum tendon jacking force results in a design load of about 96 percent of the nominal ultimate strength of the tendon. This number compares well with the maximum attainable jacking force, which is limited by the anchor efficiency factor.

Figure C5.9.5.4.4a-1—In-Plane Forces in a Soffit Blister

The radial component from the longitudinal web stress in the concrete due to the compression in the cylindrical web must be subtracted.

Figure C5.9.5.4.4a-2—In-Plane Force Effects in Curved Girders Due to Horizontally Curved Tendons

5.9.5.4.4b—Shear Resistance to Pullout

The shear resistance per unit length of the concrete cover against pullout by deviation forces, V_r , shall be taken as:

$$V_r = \phi V_n \quad (5.9.5.4.4b-1)$$

in which:

$$V_n = 0.15d_{eff}\lambda\sqrt{f'_{ci}} \quad (5.9.5.4.4b-2)$$

where:

- ϕ = resistance factor for shear, 0.75
- V_n = nominal shear resistance of two shear planes per unit length (kips/in.)
- d_{eff} = one-half the effective length of the failure plane in shear and tension for a curved element (in.)
- λ = concrete density modification factor, as specified in Article 5.4.2.8
- f'_{ci} = design concrete compressive strength at time of application of tendon force (ksi)

For single duct stack or for $s_{duct} < d_{duct}$, d_{eff} , shown in Detail (a) in Figure 5.9.5.4.4b-1, shall be taken as:

$$d_{eff} = d_c + \frac{d_{duct}}{4} \quad (5.9.5.4.4b-3)$$

For $s_{duct} \geq d_{duct}$, d_{eff} shall be taken as the lesser of the following based on Paths 1 and 2 shown in Detail (b) in Figure 5.9.5.4.4b-1:

$$d_{eff} = t_w - \frac{d_{duct}}{2} \quad (5.9.5.4.4b-4)$$

C5.9.5.4.4b

The two shear planes for which Eq. 5.9.5.4.4b-2 gives V_n are as indicated in Figure 5.9.5.4.4b-1 for single and multiple tendons.

Where a staggered or side-by-side group of ducts is located side by side in a single web, all possible shear and tension failure planes should be considered in determining d_{eff} .

$$d_{eff} = d_c + \frac{d_{duct}}{4} + \frac{\sum s_{duct}}{2} \quad (5.9.5.4.4b-5)$$

where:

- d_c = minimum concrete cover over the tendon duct (in.)
 d_{duct} = outside diameter of post-tensioning duct (in.)
 t_w = web thickness (in.)
 s_{duct} = clear distance between tendon ducts in vertical direction (in.)

Figure 5.9.5.4.4b-1—Definition of d_{eff}

If the factored in-plane deviation force exceeds the factored shear resistance of the concrete cover, as specified in Eq. 5.9.5.4.4b-1, fully anchored stirrups and duct ties to resist the in-plane deviation forces shall be provided in the form of either nonprestressed or prestressed reinforcement. The duct ties shall be anchored beyond the ducts either by in-plane 90 degree hooks or by hooking around the vertical bar.

Additional information on deviation forces can be found in Nutt et al. (2008) and Van Landuyt (1991).

Common practice is to limit the stress in the duct ties to 36.0 ksi at the maximum unfactored tensile force.

A generic stirrup and duct tie detail is shown in Figure C5.9.5.4.4b-1. Small diameter reinforcing bars should be used for better anchorage of these bars. There have been no reported web failures where this detail has been used.

Figure C5.9.5.4.4b-1—Generic Duct Tie Detail

5.9.5.4.4c—Cracking of Cover Concrete

When the clear distance between ducts oriented in a vertical column is less than 1.5 in., the ducts shall be

C5.9.5.4.4c

Figure C5.9.5.4.4c-1 illustrates the concept of an unreinforced cover concrete beam to be investigated for

considered stacked. Resistance to cracking shall be investigated at the ends and at midheight of the unreinforced cover concrete.

The applied local moment per unit length at the ends of the cover shall be taken as:

$$M_{end} = \frac{\left(\frac{\Sigma F_{u-in}}{h_{ds}} \right) h_{ds}^2}{12} \quad (5.9.5.4.4c-1)$$

and the applied local moment per unit length at the midheight of the cover shall be taken as:

$$M_{mid} = \frac{\left(\frac{\Sigma F_{u-in}}{h_{ds}} \right) h_{ds}^2}{24} \quad (5.9.5.4.4c-2)$$

where:

h_{ds} = height of the duct stack, as shown in Figure C5.9.5.4.4c-1

Tensile stresses in the unreinforced concrete cover resulting from Eqs. 5.9.5.4.4c-1 and 5.9.5.4.4c-2 shall be combined with the tensile stresses from regional bending of the web as defined in Article 5.9.5.4.4d to evaluate the potential for cracking of the cover concrete. If combined tensile stresses exceed the cracking stresses given by Eq. 5.9.5.4.4c-3, ducts shall be restrained by stirrup and duct tie reinforcement.

The design flexural cracking stress of the hypothetical unreinforced concrete beam consisting of the cover concrete over the inside face of a stack of horizontally curved post-tensioned tendons, f_{cr} , shall be determined as follows:

$$f_{cr} = \phi f_r \quad (5.9.5.4.4c-3)$$

in which:

$$\phi = 0.85$$

where:

f_r = modulus of rupture of concrete (ksi)

5.9.5.4.4d—Regional Bending

The regional flexural effects of in-plane forces at the strength limit state shall be taken as:

$$M_u = \frac{\phi_{cont} \Sigma F_{u-in} h_c}{4} \quad (5.9.5.4.4d-1)$$

where:

ϕ_{cont} = 0.6 girder web continuity factor for interior webs; 0.7 girder web continuity factor for exterior webs

cracking. Experience has shown that a vertical stack of more than three ducts can result in cracking of the cover concrete. When more than three ducts are required, it is recommended that at least 1.5 in. spacing be provided between the upper and lower ducts of the two stacks.

The resistance factor is based on successful performance of curved post-tensioned box girder bridges in California.

Figure C5.9.5.4.4c-1—Hypothetical Unreinforced Concrete Cover Beam

C5.9.5.4.4d

When determining tensile stresses for the purpose of evaluating the potential for cracking of the cover concrete as specified in Article 5.9.5.4.4c, the effect of regional bending is combined with bending of the local concrete cover beam. It is recommended that the effect of stirrups in resisting bending be ignored, and that the ducts be considered as voids in the transverse section of the webs.

The wedging action of strands within the duct due to vertical curvature of the tendon can exacerbate tendon pullout resulting from horizontal curvature of the

h_c = span of the web between the top and bottom slabs measured along the axis of the web, as shown in Figure C5.9.5.4.4a-2

For curved girders, the local flexural and shear effects of out-of-plane forces as described in Article 5.9.5.4.5 shall be evaluated.

When curved ducts for tendons other than those crossing at approximately 90 degrees are located so that the direction of the radial force from one tendon is toward another, confinement of the ducts shall be provided by:

- spacing the ducts to ensure adequate nominal shear resistance, as specified in Eq. 5.9.5.4.4b-1; or
- providing confinement reinforcement to resist the radial force.

5.9.5.4.5—Out-of-Plane Force Effects

Out-of-plane force effects due to the wedging action of strands against the duct wall may be estimated as:

$$F_{u-out} = \frac{P_u}{\pi R} \quad (5.9.5.4.5-1)$$

where:

F_{u-out} = out-of-plane force effect per unit length of tendon (kip/ft)
 P_u = factored tendon force, as specified in Article 3.4.3 (kip)
 R = radius of curvature of the tendon in a vertical plane at the considered location (ft)

If the factored shear resistance given by Eq. 5.9.5.4.4b-1 is not adequate, local confining reinforcement shall be provided throughout the curved tendon segments to resist all of the out-of-plane forces, preferably in the form of spiral reinforcement.

tendon as described in Articles 5.9.5.4.4b and 5.9.5.4.4c.

C5.9.5.4.5

Out-of-plane forces in multistrand, post-tensioning tendons are caused by the spreading of the strands or wires within the duct, as shown in Figure C5.9.5.4.5-1. Small out-of-plane forces may be resisted by concrete in shear; otherwise, spiral reinforcement is most effective to resist out-of-plane forces. In horizontally curved bridges, out-of-plane forces due to the vertical curvature of tendons should be added to in-plane forces resulting from horizontal curvature of the tendons. Additional information can be found in Nutt (2008).

TENDON AT STRESSING LOAD

Large radial forces due to "flattening out" of tendon bundle initiate cracking in vicinity of sharpest curvature.

FAILURE

Side face rupture at point of sharpest curvature.

Figure C5.9.5.4.5-1—Effects of Out-of-Plane Forces

5.9.5.5—External Tendon Supports

Unless a vibration analysis indicates otherwise, the unsupported length of external tendons shall not exceed 25.0 ft. External tendon supports in curved concrete box girders shall be located far enough away from the web to prevent the free length of tendon from bearing on the web at locations away from the supports. Where deviation saddles are required for this purpose, they shall be designed in accordance with Article 5.9.5.6.9.

5.9.5.6—Post-Tensioned Anchorage Zones

5.9.5.6.1—General

For bonded systems, bond transfer lengths between anchorages and critical zones where the full prestressing force is required under strength or extreme event loads shall normally be sufficient to develop the minimum specified ultimate strength of the prestressing steel. When anchorages or couplers are located at, or near, critical sections under strength or extreme event loads, the ultimate strength required of the bonded tendons shall not exceed the ultimate capacity of the tendon assembly, including the anchorage and coupler, tested in an unbonded state.

Anchorages shall be designed at the strength limit states for the factored jacking forces, as specified in Article 3.4.3.

For anchorage zones at the end of a component or segment, the transverse dimensions may be taken as the depth and width of the section but not larger than the longitudinal dimension of the component or segment. The longitudinal extent of the anchorage zone in the direction of the tendon shall not be less than the greater of the transverse dimensions of the anchorage zone and shall not be taken as more than one and one-half times that dimension.

For intermediate anchorages, the anchorage zone shall be considered to extend in the direction opposite to the anchorage force for a distance not less than the larger of the transverse dimensions of the anchorage zone.

C5.9.5.6.1

The purpose of locating anchorages and couplers away from critical zones where the full strength of the tendon is required under strength or extreme event loads is to assure the full capacity of the tendon can be developed and is not potentially reduced by anchorages or couplers. Testing shall establish the capacity of anchorages and couplers located within a bond transfer length of any critical section as this capacity may be less than that of the tendon itself. The *AASHTO LRFD Bridge Construction Specifications* require anchorages to develop a minimum of 95 percent of actual ultimate tensile strength of the prestressing steel. Therefore, using 95 percent of the guaranteed ultimate tensile strength would be acceptable for design purposes in lieu of additional testing.

With slight modifications, the provisions of Article 5.9.5.6 are also applicable to the design of reinforcement under high-load capacity bearings.

The anchorage zone is geometrically defined as the volume of concrete through which the concentrated prestressing force at the anchorage device spreads transversely to a more linear stress distribution across the entire cross-section at some distance from the anchorage device.

Within the anchorage zone, the assumption that plane sections remain plane is not valid.

The dimensions of the anchorage zone are based on the principle of St. Venant. Provisions for components with a length smaller than one of its transverse dimensions were included to address cases such as transverse prestressing of bridge decks, as shown in Figure C5.9.5.6.1-1.

a) Principal Tensile Stresses and the General Zone

b) Principal Compressive Stresses and the Local Zone

Figure C5.9.5.6.1-2—General Zone and Local Zone

5.9.5.6.2—General Zone

The extent of the general zone shall be taken as identical to that of the overall anchorage zone including the local zone, defined in Article 5.9.5.6.1.

Design of general zones shall comply with the requirements of Article 5.9.5.6.5.

5.9.5.6.3—Local Zone

Design of local zones shall either comply with the requirements of Article 5.8.4.4 or be based on the results of acceptance tests as specified in Article 5.8.4.4.3 and described in Article 10.3.2.3 of the *AASHTO LRFD Bridge Construction Specifications*.

For design of the local zone, the effects of high bearing pressure and the application of confining reinforcement shall be considered.

Anchorage devices based on the acceptance test of Article 10.3.2.3 of the *AASHTO LRFD Bridge Construction Specifications* shall be referred to as “special anchorage devices.”

C5.9.5.6.2

In many cases, the general zone and the local zone can be treated separately, but for small anchorage zones, such as in slab anchorages, local zone effects (e.g., high bearing and confining stresses), and general zone effects (e.g., tensile stresses due to spreading of the tendon force) may occur in the same region. The designer should account for the influence of overlapping general zones.

C5.9.5.6.3

The local zone is defined as either the rectangular prism, or, for circular or oval anchorages, the equivalent rectangular prism of the concrete surrounding and immediately ahead of the anchorage device and any integral confining reinforcement. The dimensions of the local zone are defined in Article 5.8.4.4.1.

The local zone is expected to resist the high local stresses introduced by the anchorage device and to transfer them to the remainder of the anchorage zone. The resistance of the local zone is more influenced by the characteristics of the anchorage device and its confining reinforcement than by either the geometry or the loading of the structure.

5.9.5.6.4—Responsibilities

The Engineer of Record shall be responsible for the overall design and approval of working drawings for the general zone, including the location of the tendons and anchorage devices, general zone reinforcement, the stressing sequence, and the design of the local zone for anchorage devices based on the provisions of Article 5.8.4.4. The local zone reinforcing for special anchorage devices shall be established by the Supplier of the anchorage device. The contract documents shall specify that all working drawings for the local zone must be approved by the Engineer of Record.

The anchorage device Supplier shall be responsible for furnishing anchorage devices that satisfy the anchor efficiency requirements of Article 10.3.2 of the *AASHTO LRFD Bridge Construction Specifications*. If special anchorage devices are used, the anchorage device Supplier shall be responsible for furnishing anchorage devices that also satisfy the acceptance test requirements of Article 5.8.4.4.3 and of Article 10.3.2.3 of the *AASHTO LRFD Bridge Construction Specifications*. This acceptance test and the anchor efficiency test shall be conducted by an independent testing agency acceptable to the Engineer of Record. The anchorage device supplier shall provide records of the acceptance test in conformance with Article 10.3.2.3.12 of the *AASHTO LRFD Bridge Construction Specifications* to the Engineer of Record and to the Constructor and shall specify auxiliary and confining reinforcement, minimum edge distance, minimum anchor spacing, and minimum concrete strength at time of stressing required for proper performance of the local zone.

The responsibilities of the Constructor shall be as specified in Article 10.4 of the *AASHTO LRFD Bridge Construction Specifications*.

5.9.5.6.5—Design of the General Zone

5.9.5.6.5a—Design Methods

For the design of general zones, the following design methods, conforming to the requirements of Article 5.9.5.6.5b, may be used:

- equilibrium-based inelastic models, generally termed the STM (illustrated in Article 5.8.2.7);
- refined elastic stress analyses, as specified in Section 4; or
- other approximate methods, such as those provided in Article 5.8.4.5, where applicable.

The effects of stressing sequence and three-dimensional effects due to concentrated jacking loads shall be investigated. Three-dimensional effects may be analyzed using three-dimensional analysis procedures or may be approximated by considering

C5.9.5.6.4

The Engineer of Record has the responsibility to indicate the location of individual tendons and anchorage devices. Should the Designer initially choose to indicate only total tendon force and eccentricity, he still retains the responsibility of approving the specific tendon layout and anchorage arrangement submitted by a post-tensioning specialist or the Contractor. The Engineer is responsible for the design of general zone reinforcement required by the approved tendon layout and anchorage device arrangement.

The use of special anchorage devices does not relieve the Engineer of Record from his responsibility to review the design and working drawings for the anchorage zone to ensure compliance with the anchorage device Supplier's specifications.

For special anchorage devices, the anchorage device Supplier has to provide information regarding all requirements necessary for the satisfactory performance of the local zone to the Engineer of Record and to the Contractor. Necessary local zone confinement reinforcement has to be specified by the Supplier.

C5.9.5.6.5a

The design methods referred to in this article are not meant to preclude other recognized and verified procedures. In many anchorage applications where substantial or massive concrete regions surround the anchorages and where the members are essentially rectangular without substantial deviations in the force flow path, the approximate procedures of Article 5.8.4.5 can be used. However, in the post-tensioning of thin sections, flanged sections, and irregular sections or where the tendons have appreciable curvature, the more general procedures of Article 5.8.2.7 and 5.8.3 may be required.

Different anchorage force combinations have a significant effect on the general zone stresses. Therefore, it is important to consider not only the final stage of a stressing sequence with all tendons stressed but also the intermediate stages.

separate submodels for two or more planes, in which case the interaction of the submodels should be considered, and the model loads and results should be consistent.

The factored concrete compressive stress for the general zone shall not exceed $0.7\phi f'_{ci}$. In areas where the concrete may be extensively cracked at ultimate due to other force effects, or if large inelastic rotations are expected, the factored compressive stress shall be limited to $0.6\phi f'_{ci}$.

The tensile strength of the concrete shall be neglected in the design of the general zone.

The nominal tensile stress of bonded reinforcement shall be limited to f_y for both nonprestressed reinforcement and bonded prestressed reinforcement. The nominal tensile stress of unbonded or debonded prestressed reinforcement shall be limited to $f_{pe} + 15,000$ psi.

The contribution of any local zone reinforcement to the strength of the general zone may be conservatively neglected in the design.

5.9.5.6.5b—Design Principles

Compressive stresses in the concrete ahead of basic anchorage devices shall satisfy the requirements of Article 5.8.4.4.2.

The compressive stresses in the concrete ahead of the anchorage device shall be investigated at a distance, measured from the concrete bearing surface, determined as the greater of the following:

- the depth to the end of the local confinement reinforcement; or
- the smaller lateral dimension of the anchorage device.

These compressive stresses may be determined using the STM of Article 5.8.2.7, an elastic stress analysis according to Article 5.8.3, or the approximate method outlined in Article 5.8.4.5.2.

The magnitude of the bursting force, T_{burst} , and its corresponding distance from the loaded surface, d_{burst} , may be determined using the STM of Article 5.8.2.7, an elastic stress analysis according to Article 5.8.3, or the approximate method outlined in Article 5.8.4.5.3. Three-dimensional effects shall be considered for the determination of the bursting reinforcement requirements.

Compressive stresses shall also be checked where geometry or loading discontinuities within or ahead of the anchorage zone may cause stress concentrations.

Resistance to bursting forces shall be provided by nonprestressed or prestressed reinforcement or in the form of spirals, hoops, or ties. This reinforcement shall resist the total bursting force. The following guidelines for the arrangement and anchorage of bursting reinforcement should apply:

The provision concerning three-dimensional effects was included to alert the Designer to effects perpendicular to the main plane of the member, such as bursting forces in the thin direction of webs or slabs. For example, in members with thin rectangular cross-sections, bursting forces not only exist in the major plane of the member but also perpendicular to it. In many cases, these effects can be determined independently for each direction, but some applications require a fully three-dimensional analysis, i.e., diaphragms for the anchorage of external tendons.

C5.9.5.6.5b

Good detailing and quality workmanship are essential for the satisfactory performance of anchorage zones. Sizes and details for anchorage zones should respect the need for tolerances on the bending, fabrication, and placement of reinforcement; the size of aggregate; and the need for placement and sound consolidation of the concrete.

The interface between the confined concrete of the local zone and the usually unconfined concrete of the general zone is critical. The provisions of this article define the location where concrete stresses should be investigated.

The bursting force is the tensile force in the anchorage zone acting ahead of the anchorage device and transverse to the tendon axis. Bursting forces are caused by the lateral spreading of the prestressing forces concentrated at the anchorage.

The guidelines for the arrangement of the bursting reinforcement direct the Designer toward reinforcement patterns that reflect the elastic stress distribution. The experimental test results show that this leads to satisfactory behavior at the service limit state by limiting the extent and opening of cracks and at the strength limit state by limiting the required amount of redistribution of forces in the anchorage zone (Sanders, 1990). A uniform distribution of the bursting reinforcement with its centroid at d_{burst} , as shown in Figure C5.9.5.6.5b-1, may be considered acceptable.

- Reinforcement is extended over the full width of the member and anchored as close to the outer faces of the member as cover permits;
- Reinforcement is distributed ahead of the loaded surface along both sides of the tendon throughout a distance taken as the lesser of $2.5 d_{burst}$ for the plane considered and 1.5 times the corresponding lateral dimension of the section, where d_{burst} is specified by Eq. 5.8.4.5.3-2;
- The centroid of the bursting reinforcement coincides with the distance d_{burst} used for the design; and
- Spacing of reinforcement is not greater than 24.0 bar diameters or 12.0 in.

The edge tension forces may be determined using the STM, procedures of Article 5.8.2.7, elastic analysis according to Article 5.8.3, or approximate methods of Article 5.8.4.5.4.

For multiple anchorages with a center-to-center spacing of less than 0.4 times the depth of the section, the spalling force shall not be taken to be less than two percent of the total factored tendon force. For larger spacings, the spalling forces shall be determined by analysis.

Edge tension forces are tensile forces in the anchorage zone acting parallel and close to the transverse edge and longitudinal edges of the member. The transverse edge is the surface loaded by the anchors. The tensile force along the transverse edge is referred to as spalling force. The tensile force along the longitudinal edge is referred to as longitudinal edge tension force.

The STM may be used for larger anchor spacings.

Figure C5.9.5.6.5b-1—Arrangement for Bursting Reinforcement

Spalling forces are induced in concentrically loaded anchorage zones, eccentrically loaded anchorage zones, and anchorage zones for multiple anchors. Longitudinal edge tension forces are induced where the resultant of the anchorage forces causes eccentric loading of the anchorage zone.

Resistance to edge tension forces shall be provided by reinforcement located close to the longitudinal and transverse edge of the concrete. Arrangement and anchorage of the edge tension reinforcement shall satisfy the following:

- specified spalling reinforcement is extended over the full width of the member;
- spalling reinforcement between multiple anchorage devices effectively ties the anchorage devices together; and
- longitudinal edge tension reinforcement and spalling reinforcement for eccentric anchorage devices are continuous; the reinforcement extends along the tension face over the full length of the anchorage zone and along the loaded face from the longitudinal edge to the other side of the eccentric anchorage device or group of anchorage devices.

For multiple anchorages, the spalling forces are required for equilibrium, and provision for adequate reinforcement is essential for the ultimate load capacity of the anchorage zone, as shown in Figure C5.9.5.6.5b-2. These tension forces are similar to the tensile tie forces existing between individual footings supporting deep walls. In most cases, the minimum spalling reinforcement specified herein will control.

Figure C5.9.5.6.5b-2—Path of Forces for Multiple Anchorages

Figure C5.9.5.6.5b-3 illustrates the location of the edge tension forces.

Figure C5.9.5.6.5b-3—Edge Tension Forces

The minimum spalling force for design is two percent of the total post-tensioning force. This value is smaller than the four percent proposed by Guyon (1953) and reflects both analytical and experimental findings showing that Guyon's values for spalling forces are rather conservative and that spalling cracks are rarely observed in experimental studies (Base et al., 1966) (Beeby, 1983).

Figure C5.9.5.6.5b-4 illustrates the reinforcement requirements for anchorage zones.

Figure C5.9.5.6b-4—Arrangement of Anchorage Zone Reinforcement

5.9.5.6.6—Special Anchorage Devices

Where special anchorage devices that do not satisfy the requirements of Article 5.8.4.4.2 are to be used, reinforcement similar in configuration and at least equivalent in volumetric ratio to the supplementary skin reinforcement permitted under the provisions of Article 10.3.2.3.4 of the *AASHTO LRFD Bridge Construction Specifications* shall be furnished in the corresponding regions of the anchorage zone.

5.9.5.6.7—Intermediate Anchorages

5.9.5.6.7a—General

Intermediate anchorages shall not be used in regions where significant tension is generated behind the anchor from other loads. Intermediate anchorages near unreinforced segment joints shall only be located where there is sufficient residual compression, f_{cb} , to resist 125 percent of the tie-back force behind the anchor. Wherever practical, blisters should be located in the corner between flange and webs or shall be extended over the full flange width or web height to form a continuous rib. If isolated blisters must be used on a flange or web, local shear bending, and direct force effects shall be considered in the design.

C5.9.5.6.7a

Intermediate anchorages are usually used in segmented construction. Locating anchorage blisters in the corner between flange and webs significantly reduces local force effects at intermediate anchorages. Lesser reduction in local effects can be obtained by increasing the width of the blister to match the full width of the flange or full depth of the web to which the blister is attached.

For flange thickness ranging from 5.0 to 9.0 in., an upper limit of 12, Grade 270 ksi, 0.5-in. diameter strands is recommended for tendons anchored in blisters supported only by the flange. The anchorage force of the tendon must be carefully distributed to the flange by reinforcement.

5.9.5.6.7b—Crack Control behind Intermediate Anchors

C5.9.5.6.7b

Unless otherwise specified herein, bonded reinforcement shall be provided to tie-back at least 25 percent of the tendon force behind the intermediate anchor into the concrete section at service limit states and any stage of construction. Stresses in this bonded reinforcement shall not exceed the lesser of the following:

- $0.6 f_y$; or
- 36.0 ksi.

If compressive stresses are generated behind the anchor, the amount of tie-back reinforcement may be reduced using Eq. 5.9.5.6.7b-1.

$$T_{ig} = 0.25P_s - f_{cb}A_{cb} \quad (5.9.5.6.7b-1)$$

where:

$$T_{ia} = \text{tie-back tension force at the intermediate anchorage (kip)}$$

P_s = unfactored tendon force(s) at the anchorage (kip)

f_{cb} = unfactored minimum compressive stress in the region behind the anchor at service limit states and any stage of construction (ksi)

A_{cb} = the area of the continuing cross-section within the extensions of the sides of the anchor plate or blister, i.e., the area of the blister or rib shall not be taken as part of the cross-section as shown in Figure C5.9.5.6.7b-2 (in.²)

Tie-back reinforcement shall be placed no further than one plate width from the tendon axis. It shall be fully anchored so that the yield strength can be developed at the base of the blister as well as a distance of one plate width ahead of the anchor. The centroid of this reinforcement shall coincide with the tendon axis, where possible. For blister and ribs, the reinforcement shall be placed in the continuing section near the face of the flange or web from which the blister or rib is projecting.

Cracks may develop in the slab or web walls, or both, immediately behind blisters and ribs due to stress concentrations caused by the anchorage force. Reinforcement proportioned to tie back 25 percent of the unfactored jacking force has been shown to provide adequate crack control (Wollmann, 1992). To ensure that the reinforcement is adequately developed at the crack location, a length of bar must be provided equal to one plate width plus one development length ahead of and one development length behind the anchor plate. This is illustrated in Figure C5.9.5.6.7b-1(a). For precast segmental bridges in which the blister is close to a joint, a hook may be used to properly develop the bar provided that the joint remains in compression locally behind the intermediate anchor for all service load combinations including any local tension behind the anchor. This is illustrated in Figure C5.9.5.6.7b-1(b).

(a) Condition with no Nearby Precast Joints

(b) Condition with Precast Joint Near Anchor Plate

Figure C5.9.5.6.7b-1—Required Length of Crack Control Reinforcement

The amount of tie-back reinforcing can be reduced by accounting for the compression in the concrete cross-section behind the anchor. Note that if the stress behind the anchor is tensile, the tie-back tension force will be $0.25P_s$ plus the tensile stress times A_{cb} . The area, A_{cb} , is illustrated in Figure C5.9.5.6.7b-2, along with other detailing requirements for the tie-back reinforcement.

Figure C5.9.5.6.7b-2—Examples of A_{cb}

5.9.5.6.7c—Blister and Rib Reinforcement

Reinforcement shall be provided throughout blisters or ribs as required for shear friction, corbel action, bursting forces, and deviation forces due to tendon curvature. This reinforcement shall extend as far as possible into the flange or web and be developed by standard hooks bent around transverse bars or equivalent. Spacing shall not exceed the smallest of blister or rib height at anchor, blister width, or 6.0 in.

Reinforcement shall be provided to resist local bending in blisters and ribs due to eccentricity of the tendon force and to resist lateral bending in ribs due to tendon deviation forces.

Reinforcement, as specified in Article 5.9.5.6.5b, shall be provided to resist tensile forces due to transfer of the anchorage force from the blister or rib into the overall structure.

5.9.5.6.8—Diaphragms

For tendons anchored in diaphragms, concrete compressive stresses shall be limited within the diaphragm as specified in Article 5.9.5.6.5b. Compressive stresses shall also be investigated at the transition from the diaphragm to webs and flanges of the member.

Reinforcement shall be provided to ensure full transfer of diaphragm anchor loads into the flanges and webs of the girder. Requirements for shear friction reinforcement between the diaphragm and web and between the diaphragm and flanges shall be checked.

Reinforcement shall also be provided to tie-back deviation forces due to tendon curvature.

5.9.5.6.9—Deviation Saddles

Deviation saddles shall be designed using the STM or using methods based on test results. A load factor of 1.7 shall be used with the maximum deviation force. If using a method based on test results, a resistance factor of 0.90 shall be used for direct tension and 0.85 shall be used for shear.

For bridges with multiple tendons and anchorages, the order of stressing should be taken into account and specified in the plans. For spans in which shorter tendons are wholly encompassed by longer tendons, it is frequently prudent to stress the longer tendons first.

C5.9.5.6.7c

This reinforcement is normally provided in the form of ties or U-stirrups, which encase the anchorage and tie it effectively into the adjacent web and flange.

C5.9.5.6.8

Diaphragms anchoring post-tensioning tendons may be designed following the general guidelines of Schlaich et al. (1987), Breen and Kashima (1991), and Wollmann (1992). A typical diaphragm anchoring post-tensioning tendons usually behaves as a deep beam supported on three sides by the top and bottom flanges and the web wall. The magnitude of the bending tensile force on the face of the diaphragm opposite the anchor can be determined using the STM or elastic analysis. Approximate methods, such as the symmetric prism suggested by Guyon (1953), do not apply.

The more general methods of Article 5.8.2.7 or Article 5.8.3 are used to determine this reinforcement.

C5.9.5.6.9

Deviation saddles are disturbed regions of the structure and can be designed using the STM. Tests of scale-model deviation saddles have provided important information on the behavior of deviation saddles regions. Design and detailing guidelines are presented in Beaupre et al. (1988).

5.10—REINFORCEMENT

5.10.1—Concrete Cover

Cover for prestressing and reinforcing steel shall not be less than that specified in Table 5.10.1-1 and modified for W/CM ratio.

Modification factors for W/CM ratio shall be the following:

- For $W/CM \leq 0.40$ 0.8
- For $0.40 < W/CM < 0.50$ 1.0
- For $W/CM \geq 0.50$ 1.2

Concrete cover and placing tolerances shall be shown in the contract documents.

Cover for pretensioned prestressing strand, anchorage hardware, metal ducts for post-tensioned tendons, and mechanical connections for reinforcing bars or post-tensioned prestressing strands shall be the same as for reinforcing steel as specified in Table 5.10.1-1.

For decks exposed to tire studs or chain wear, additional cover shall be used to compensate for the expected loss in concrete depth due to abrasion, as specified in Article 2.5.2.4.

Minimum cover to main bars shall be 1.0 in.

Cover to ties and stirrups may be 0.5 in. less than the values specified in Table 5.10.1-1 for main bars but shall not be less than 1.0 in. except for precast soffit form panels noted in the table below.

For bundled bars, the minimum concrete cover in noncorrosive atmosphere shall be equal to the equivalent diameter of the bundle, but need not be greater than 2.0 in.; except for concrete cast against and permanently exposed to noncorrosive soil, where the minimum cover shall be 3.0 in.

C5.10.1

Minimum cover is necessary for durability and prevention of splitting due to bond stresses and to provide for placing tolerance. Some Owners have cover requirements exceeding those in Table 5.10.1-1, especially for severe conditions such as proximity to coastal environments.

There is considerable evidence that the durability of reinforced concrete exposed to saltwater, deicing salts, or sulfates is appreciably improved if, as recommended by ACI 318-14, either or both the cover over the reinforcement is increased or the W/CM ratio is limited to 0.40. If materials, with reasonable use of admixtures, will produce a workable concrete with W/CM ratios lower than those listed in the *AASHTO LRFD Bridge Construction Specifications*, the contract documents should alter those recommendations appropriately.

The specified strengths shown in the *AASHTO LRFD Bridge Construction Specifications* are generally consistent with the W/CM ratios shown. However, it is possible to satisfy one without the other. Both are specified because W/CM ratio is a dominant factor contributing to both durability and strength; simply obtaining the strength needed to satisfy the design assumptions may not ensure adequate durability.

The concrete cover modification factor used in conjunction with Table 5.10.1-1 recognizes the decreased permeability resulting from a lower W/CM ratio.

“Corrosive” water or soil contains greater than or equal to 500 parts per million (ppm) of chlorides. Sites that are considered corrosive due solely to sulfate

content greater than or equal to 2,000 ppm and/or a pH of less than or equal to 5.5 should be considered noncorrosive in determining minimum cover.

Table 5.10.1-1—Minimum Cover for Main Reinforcing Steel (in.)

Situation	Reinforcing Material Category		
	A	B	C
Severe to Moderate Exposure			
Direct exposure to salt water	4.0	2.5	2.5
Cast against earth	3.0	2.0	2.0
Coastal	3.0	2.0	2.0
Exposure to deicing salts	2.5	2.0	1.5
Deck surfaces subject to tire stud or chain wear	2.5	2.5	2.0
Other than noted above	2.0	2.0	1.5
Limited Exposure			
Other than noted below			
• Up to #11 bar			
• #14 and #18 bars	1.5	1.0	1.0
	2.0	2.0	2.0
Bottom of cast-in-place slabs			
• Up to #11 bar	1.0	1.0	1.0
• #14 and #18 bars	2.0	2.0	2.0
Precast soffit form panels	0.8	0.8	0.8
Piling			
Precast reinforced piles			
• Noncorrosive environments	2.0	1.5	1.0
• Corrosive environments	3.0	2.5	2.0
Precast prestressed piles	2.0	1.0	1.0
Cast-in-place piles			
• Noncorrosive environments	2.0	1.5	1.5
• Corrosive environments	3.0	2.5	2.0
• Shells	2.0	1.5	1.0
• Auger-cast, tremie concrete, or slurry construction	3.0	2.5	2.0
Precast Culverts			
• Top slabs used as a driving surface	2.5	2.0	1.5
• Top slabs with less than 2.0 ft of fill	2.0	1.5	1.0
• All other members	1.0	1.0	1.0

Category A—Uncoated reinforcing steel meeting AASHTO M 31M/M 31

Category B—Epoxy coated or galvanized meeting ASTM A775/A775M

Category C—Materials meeting AASHTO M 334M/M 334

5.10.2—Hooks and Bends

5.10.2.1—Standard Hooks

For the purpose of these specifications, the term “standard hook” shall mean one of the following:

- For longitudinal reinforcement:
 - (a) 180-degree bend, plus a $4.0d_b$ extension, but not less than 2.5 in. at the free end of the bar, or
 - (b) 90-degree bend, plus a $12.0d_b$ extension at the free end of the bar.
- For transverse reinforcement:
 - (a) #5 bar and smaller—90-degree bend, plus a $6.0d_b$ extension at the free end of the bar;
 - (b) #6, #7, and #8 bars—90-degree bend, plus a $12.0d_b$ extension at the free end of the bar; and
 - (c) #8 bar and smaller—135-degree bend, plus a $6.0d_b$ extension at the free end of the bar.

where:

d_b = nominal diameter of reinforcing bar (in.)

Standard hooks may be used with reinforcing steel having a specified minimum yield strength between 75.0 and 100 ksi for elements and connections specified in Article 5.4.3.3 only if ties specified in Article 5.10.8.2.4 are provided.

5.10.2.2—Seismic Hooks

Seismic hooks meeting the requirements of Article 5.11.4.1.4 shall be used for transverse reinforcement in regions of expected plastic hinges and elsewhere as indicated in the contract documents.

5.10.2.3—Minimum Finished Bend Diameters

The finished diameter of a bar bend, measured on the inside of the bar, shall not be less than that specified in Table 5.10.2.3-1, except for galvanized bars.

Table 5.10.2.3-1—Minimum Finished Bend Diameters

Bar Size and Use	Minimum Finished Diameter
#3 through #5—General	$6.0d_b$
#3 through #5—Stirrups and Ties	$4.0d_b^*$
#6 through #8	
#9, #10, and #11	$6.0d_b$
#14 and #18	$8.0d_b$
	$10.0d_b^{**}$

C5.10.2.1

These requirements are similar to the requirements of ACI 318-19 and the Concrete Reinforcing Steel Institute's (CRSI's) *Manual of Standard Practice*.

Tests by Shahrooz et al. (2011) showed that standard hooks are adequate for reinforcement with specified minimum yield strengths between 75.0 and 100 ksi if transverse, confining reinforcement as specified in Article 5.10.8.2.4 is provided.

C5.10.2.3

For bend testing, ASTM A615/A615M requires a pin diameter of $5.0d_b$ (#3, #4, and #5 bars) for bending Grade 80 or 100 stirrup and tie reinforcement, while a pin diameter of $3.5d_b$ is still required for Grade 60 stirrup and tie reinforcement. The increased pin diameter results in changes to the recommended finished bend diameters for the higher grades. If the Owner is using such bars, the plans and specifications should address those requirements. For all other bar sizes and uses, the minimum diameters specified in the table apply for all grades of reinforcement. Note that epoxy coated reinforcing bars should also follow this guidance.

The minimum finished bend diameter can be used directly from the table for ASTM A706/A706M, Grades 60 and 80; A955/A955M, Grades 60, 75, and 80; and A1035/A1035M, Grades 100 and 120.

*For ASTM A615/A615M, Grade 80 and 100 bars, minimum finished diameter is $5.0d_b$.

**Due to safety concerns, CRSI does not recommend bending bars larger than #14 with grade designation of Grade 75 or higher.

The inside diameter of bend for stirrups and ties in plain or deformed welded wire reinforcement shall not be less than $4.0d_b$ for deformed wire larger than D6 and $2.0d_b$ for all other wire sizes. Bends with inside diameters of less than $8.0d_b$ shall not be located less than $4.0d_b$ from the nearest welded intersection.

For galvanized bars meeting ASTM A767, the finished bar bend diameter, measured on the inside of the bar, shall not be less than that specified in Table 5.10.2.3-2.

Table 5.10.2.3-2—Galvanized Bars—Minimum Finished Bend Diameter

Bar Size and Use	Minimum Finished Diameter
#3 through #6	$6.0d_b$
#7 through #8	$8.0d_b$
#9, #10, and #11	$8.0d_b$
#14 and #18	$10.0d_b$ *

Note that galvanized stirrups and ties cannot be bent to the tighter diameters noted in Table 5.10.2.3-1.

* Due to safety concerns, CRSI does not recommend bending bars larger than #14 with grade designation of Grade 75 or higher.

5.10.3—Spacing of Reinforcement

5.10.3.1—Minimum Spacing of Reinforcing Bars

5.10.3.1.1—Cast-in-Place Concrete

For cast-in-place concrete, the clear distance between parallel bars in a layer shall not be less than the largest of the following:

- 1.5 times the nominal diameter of the bars;
- 1.5 times the maximum size of the coarse aggregate; or
- 1.5 in.

To maintain uniformity and simplicity of fabrication for stirrups and ties across all grades of #3, #4, and #5 reinforcing bars, CRSI chose to recommend a finished bend diameter for all grades of reinforcing bars, with a minimum of $5.0d_b$. Owners should be aware that the CRSI *Manual of Standard Practice* (2018) notes stirrups and ties fabricated to the AASHTO required finished bend diameter of $4.0d_b$ would be considered a ‘special order’ item; note that such bars still satisfy the $3.5d_b$ minimum pin diameter per ASTM. Owners should ensure the bend requirements are appropriately communicated in contract documents.

The term “finished” has been added to Table 5.10.2.3-1 and the Article for clarity. The CRSI *Manual of Standard Practice* (2018) uses both of the terms “Bend Test Pin Diameter” and “Finished Bend Diameter”, while ACI 318 and these Specifications only refer to the “Finished Bend Diameter,” and ASTM A615/A615M only refers to the “Pin Diameter for Bend Tests.”

ASTM A767 notes that if reinforcing bars are fabricated to smaller finished bend diameters than those given in Table 5.10.2.3-2, they must be stress relieved at a temperature of 900 to 1050°F for 1 hour per inch of bar diameter. It is also noted that for reinforcing bars fabricated after galvanizing, some cracking and flaking of the galvanized coating can be expected.

5.10.3.1.2—Precast Concrete

For precast concrete manufactured under plant control conditions, the clear distance between parallel bars in a layer shall not be less than the largest of the following:

- the nominal diameter of the bars;
- 1.33 times the maximum size of the coarse aggregate; or
- 1.0 in.

5.10.3.1.3—Multilayers

Except in decks where parallel reinforcement is placed in two or more layers, with clear distance between layers not exceeding 6.0 in., the bars in the upper layers shall be placed directly above those in the bottom layer, and the clear distance between layers shall not be less than 1.0 in. or the nominal diameter of the bars.

5.10.3.1.4—Splices

The clear distance limitations between bars that are specified in Articles 5.10.3.1.1 and 5.10.3.1.2 shall also apply to the clear distance between a contact lap splice and adjacent splices or bars.

5.10.3.1.5—Bundled Bars

The number of parallel reinforcing bars bundled in contact to act as a unit shall not exceed four in any one bundle, except that in flexural members, the number of bars larger than #11 shall not exceed two in any one bundle.

Bundled bars shall be enclosed within stirrups, ties, spirals, or hoops.

Individual bars in a bundle, cut off within the span of a member, shall be terminated at different points with at least a 40-bar diameter stagger. Where spacing limitations are based on bar size, a unit of bundled bars shall be treated as a single bar of a diameter derived from the equivalent total area.

5.10.3.2—Maximum Spacing of Reinforcing Bars

Unless otherwise specified, the spacing of the reinforcement in walls and slabs shall not be greater than the lesser of the following:

- 1.5 times the thickness of the member; or
- 18.0 in.

The maximum spacing of transverse reinforcement for compression members shall be as specified in Article 5.10.4.

C5.10.3.1.5

Bundled bars should be tied, wired, or otherwise fastened together to ensure that they remain in their relative position, regardless of their inclination.

The maximum spacing of transverse reinforcement for flexural members shall be as specified in Article 5.10.5.

The maximum spacing of shrinkage and temperature reinforcement shall be as specified in Article 5.10.6.

5.10.4—Transverse Reinforcement for Compression Members

5.10.4.1—General

The provisions of Article 5.10.8 shall also apply to design and detailing in Seismic Zones 2, 3, and 4.

Transverse reinforcement for compression members may consist of spirals, hoops, or ties and cross-ties.

For elements and connections specified in Article 5.4.3.3, spirals, hoops, ties and cross-ties may be designed for specified minimum yield strengths up to 100 ksi.

5.10.4.2—Spirals

Spiral reinforcement for compression members other than piles shall consist of one or more evenly spaced continuous spirals of either deformed or plain bar or wire with a minimum diameter of 0.375 in. The reinforcement shall be arranged so that all primary longitudinal reinforcement is contained on the inside of, and in contact with, the spirals.

The clear spacing between the bars of the spiral shall not be less than the greater of the following:

- 1.0 in.; or
- 1.33 times the maximum size of the aggregate.

The center-to-center spacing shall not exceed 6.0 times the diameter of the longitudinal bars or 6.0 in.

Except as specified in Articles 5.11.3 and 5.11.4.1 for Seismic Zones 2, 3, and 4, spiral reinforcement shall extend from the footing or other support to the level of the lowest horizontal reinforcement of the supported members.

Anchorage of spiral reinforcement shall be provided by 1.5 extra turns of spiral bar or wire at each end of the spiral unit. For Seismic Zones 2, 3, and 4, the extension of transverse reinforcement into connecting members shall meet the requirements of Article 5.11.4.3.

Splices in spiral reinforcement may be one of the following:

- Lap splices of 48.0 uncoated bar diameters, 72.0 coated bar diameters, or 48.0 wire diameters;
- approved mechanical connectors; or
- approved welded splices.

C5.10.4.1

Article 5.11.2 applies to Seismic Zone 1 but has no additional requirements for transverse reinforcement for compression members.

Spirals, hoops, and ties and cross-ties with specified minimum yield strengths of up to 100 ksi are permitted in Seismic Zone 1 only, based on research by Shahrooz et al. (2011).

5.10.4.3—Ties

The following requirements for transverse reinforcement may be used for design concrete compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi.

In tied compression members, all longitudinal bars or bundles shall be enclosed by ties that shall be at least:

- #3 bars for #10 or smaller bars;
- #4 bars for #11 or larger bars; and
- #4 bars for bundled bars.

The spacing of ties along the longitudinal axis of the compression member with single bars or bundles of #9 bars or smaller shall not exceed the lesser of the following:

- The least dimension of the member; or
- 12.0 in.

Where two or more bars larger than #10 are bundled together, the spacing of ties along the longitudinal axis of the compression member shall not exceed the lesser of the following:

- Half the least dimension of the member; or
- 6.0 in.

The clear spacing between tie reinforcement shall not be less than the greater of the following:

- 1.0 in.; or
- 1.33 times the maximum size of the aggregate.

Deformed wire or welded wire reinforcement of equivalent area may be used instead of bars.

For columns that are not designed for plastic hinging, the spacing of laterally restrained longitudinal bars or bundles shall not exceed 24.0 in. measured along the perimeter tie. A restrained bar or bundle is one that has lateral support provided by the corner of a tie having an included angle of not more than 135 degrees or is restrained by a cross-tie. Cross-ties with a 135-degree hook at one end and a 90-degree hook at the other end shall be alternated so that the 90-degree hooks are not adjacent to each other both vertically and horizontally.

Within potential plastic hinge regions of columns or pile bents, the spacing of laterally restrained longitudinal bars or bundles shall not exceed 12.0 in. measured along the perimeter tie, and the tie reinforcement shall meet the requirements of Articles 5.11.4.1.4 through 5.11.4.1.6.

C5.10.4.3

The revision to reduce the spacing, from 48.0 in. to 24.0 in., for laterally-restrained longitudinal bars or bundles is to bring the language back to the original intent of the 1980 Interim Revisions to the AASHTO Standard Specifications.

Figure C5.10.4.3-1 illustrates the placement of ties and cross-ties in compression members that are not designed for plastic hinging. Cross-ties in locations not designed for plastic hinging should have standard hooks.

Figure C5.10.4.3-1—Acceptable Tie and Cross-Tie Arrangements Outside Potential Plastic Hinge Regions

Columns in Seismic Zones 2, 3, and 4 are designed for plastic hinging. The potential plastic hinge region is defined in Article 5.11.4.1.3. Additional requirements for transverse reinforcement for bridges in Seismic Zones 2, 3, and 4 are specified in Articles 5.11.3 and 5.11.4.1. Plastic hinging may be used as a design strategy for other extreme events, such as ship collision. Figure C5.10.4.3-2 illustrates the placement of ties in compression members that are designed for plastic hinging.

Lap splices of ties shall not be permitted in Seismic Zones 2, 3, and 4 unless the overlapping bars are enclosed over the length of the splice by the hooks of at least four cross-ties located at intersections of the transverse reinforcing bars and longitudinal bars.

Except as specified in Article 5.11.4.1 for Seismic Zones 3 and 4, ties shall be located vertically not more than half a tie spacing above the footing or other support and not more than half a tie spacing below the lowest horizontal reinforcement in the supported member.

Figure C5.10.4.3-2—Acceptable Tie Arrangement in Potential Plastic Hinge Regions

5.10.4.4—Hoops

Where the longitudinal bars or bundles are located around the periphery of a circle, hoops may be used with splices in the hoop staggered and without the need for cross-ties.

Hoop reinforcement for compression members other than piles shall consist of deformed or plain bar. The reinforcement shall be arranged so that all primary longitudinal reinforcement is contained on the inside of, and in contact with, the hoops.

The clear spacing between hoop reinforcement shall not be less than the greater of the following:

- 1.0 in.; or
- 1.33 times the maximum size of the aggregate.

The center-to-center spacing shall not exceed 6.0 times the diameter of the longitudinal bars or 6.0 in. Except as specified in Articles 5.11.3 and 5.11.4.1 for Seismic Zones 2, 3, and 4, hoop reinforcement shall extend from the footing or other support to the level of the lowest horizontal reinforcement of the supported members.

For Seismic Zones 2, 3, and 4, the extension of hoop reinforcement into connecting members shall meet the requirements of Article 5.11.4.3.

Splices in hoop reinforcement may be one of the following:

- full-mechanical connectors;
- full-welded splices;

C5.10.4.4

Figure C5.10.4.4-1 illustrates hoop reinforcement utilizing overlapping ends terminating with standard hooks that engage longitudinal bars. Vertical splitting and loss of hoop restraint are possible where the overlapped ends of adjacent hoops are anchored at a single longitudinal bar.

Figure C5.10.4.4-1—Hoops with Overlapping Ends Terminating with Hooks

- overlapping ends terminating with standard hooks that engage longitudinal bars. The lapping portion shall be greater than 6.0 in. Adjacent hoops shall be staggered in such a manner to avoid engaging the same longitudinal bars with end hook anchorages; or
- lap splices for Seismic Zone 1 only—lap splices in adjacent hoops shall be staggered.

5.10.5—Transverse Reinforcement for Flexural Members

Compression reinforcement in flexural members, except deck slabs, shall be enclosed by ties or stirrups satisfying the size and spacing requirements of Article 5.10.4 or by welded wire reinforcement of equivalent area.

5.10.6—Shrinkage and Temperature Reinforcement

Reinforcement for shrinkage and temperature stresses shall be provided near surfaces of concrete exposed to daily temperature changes and in structural mass concrete. Temperature and shrinkage reinforcement to ensure that the total reinforcement on exposed surfaces is not less than that specified herein.

Reinforcement for shrinkage and temperature may be in the form of bars, welded wire reinforcement, or prestressing tendons.

For bars or welded wire reinforcement, the area of reinforcement per foot, on each face and in each direction, shall satisfy the following:

$$A_s \geq \frac{1.30bh}{2(b+h)f_y} \quad (5.10.6-1)$$

except that:

$$0.11 \leq A_s \leq 0.60 \quad (5.10.6-2)$$

where:

- A_s = area of reinforcement in each direction and each face (in.²/ft)
- b = least width of component section (in.)
- h = least thickness of component section (in.)
- f_y = specified minimum yield strength of reinforcement ≤ 75.0 ksi

Where the least dimension varies along the length of wall, footing, or other component, multiple sections should be examined to represent the average condition at each section. Spacing shall not exceed the following:

- 12.0 in. for walls and footings greater than 18.0 in. thick
- 12.0 in. for other components greater than 36.0 in. thick

C5.10.6

The comparable equation in ACI 318-14 was written for slabs with the reinforcement being distributed equally to both surfaces of the slabs.

The requirements of this Article are based on ACI 318-14 and 207.2R (2007). The coefficient in Eq. 5.10.6-1 is the product of 0.0018, 60.0 ksi, and 12.0 in./ft and, therefore, has the units kips/in.-ft.

Eq. 5.10.6-1 is written to show that the total required reinforcement, $A_s = 0.0018bh$, is distributed uniformly around the perimeter of the component. It provides a more uniform approach for components of any size. For example, a 30.0 ft high $\times$ 1.0 ft thick wall section requires 0.126 in.²/ft in each face and each direction; a 4.0 ft $\times$ 4.0 ft component requires 0.260 in.²/ft in each face and each direction; and a 5.0 ft $\times$ 20.0 ft footing requires 0.520 in.²/ft in each face and each direction. For circular or other shapes, the equation becomes:

$$A_s \geq \frac{1.3A_g}{\text{Perimeter}(f_y)} \quad (C5.10.6-1)$$

Permanent prestress of 0.11 ksi is equivalent to the resistance of the steel specified in Eq. 5.10.6-1 at the strength limit state. The 0.11 ksi prestress should not be added to that required for the strength or service limit states. It is a minimum requirement for shrinkage and temperature crack control.

The spacing of stress-relieving joints should be considered in determining the area of shrinkage and temperature reinforcement.

- For all other situations, 3.0 times the component thickness but not less than 18.0 in.

For components 6.0 in. or less in thickness the minimum steel specified may be placed in a single layer. Shrinkage and temperature steel shall not be required for:

- End face of walls 18.0 in. or less in thickness
- Side faces of buried footings 36.0 in. or less in thickness
- Faces of all other components, with smaller dimension less than or equal to 18.0 in.

If prestressing tendons are used as steel for shrinkage and temperature reinforcement, the tendons shall provide a minimum average compressive stress of 0.11 ksi on the gross concrete area through which a crack plane may extend, based on the effective prestress at the service limit state. Spacing of tendons should not exceed either 72.0 in. or the distance specified in Article 5.9.4.2. Where the spacing is greater than 54.0 in., bonded reinforcement shall be provided between tendons, for a distance equal to the tendon spacing.

5.10.7—Reinforcement for Hollow Rectangular Compression Members

5.10.7.1—General

The area of longitudinal reinforcement in the cross-section shall not be less than 0.01 times the gross area of concrete.

Two layers of reinforcement shall be provided in each wall of the cross-section, one layer near each face of the wall. The areas of reinforcement in the two layers shall be approximately equal.

5.10.7.2—Spacing of Reinforcement

The center-to-center spacing of longitudinal reinforcing bars shall be no greater than the lesser of 1.5 times the wall thickness or 18.0 in.

The center-to-center spacing of transverse reinforcing bars shall be no greater than the lesser of 1.25 times the wall thickness or 12.0 in.

5.10.7.3—Ties and Cross-Ties

Cross-ties shall be provided between layers of reinforcement in each wall. The cross-ties shall include a standard 135-degree hook at one end and a standard 90-degree hook at the other end. Cross-ties shall be alternated so that hooks with the same bend angle are not adjacent to each other both vertically and horizontally. Cross-ties shall be located at bar grid intersections. Intersections of longitudinal reinforcing bars and transverse reinforcing bars shall be enclosed

Surfaces of interior walls of box girders need not be considered to be exposed to daily temperature changes.

See also Article 12.14.5.8 for additional requirements for three-sided buried structures.

by the hook of a cross-tie at a spacing no greater than 24.0 in.

Where details permit, the longitudinal reinforcing bars in the corners of the cross-section shall be enclosed by ties. If ties cannot be provided, pairs of U-shaped bars with legs at least twice as long as the wall thickness and oriented 90 degrees to one another may be used.

For segmentally constructed members, additional cross-ties shall be provided along the top and bottom edges of each segment. The cross-tie shall be placed so as to link the ends of each pair of internal and external longitudinal reinforcing bars in the walls of the cross-section.

Post-tensioning ducts located in the corners of the cross-section shall be anchored into the corner regions with duct ties having a 90-degree bend at each end to enclose at least one longitudinal bar near the outer face of the cross-section.

5.10.7.4—Splices

Transverse reinforcing bars may be joined at the corners of the cross-section by overlapping 90-degree bends. Straight lap splices of transverse reinforcing bars shall not be permitted unless the overlapping bars are enclosed over the length of the splice by the hooks of at least four cross-ties located at intersections of the transverse reinforcing bars and longitudinal reinforcing bars.

5.10.8—Development and Splices of Reinforcement

5.10.8.1—General

The provisions of Articles 5.10.8.2.1, 5.10.8.2.4, 5.10.8.2.7, and 5.10.8.4.3a are valid for reinforcing bars in concrete with design compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi, subject to the limitations as specified in each of these articles.

5.10.8.1.1—Basic Requirements

This Article shall be taken as applicable to nonprestressed reinforcement having a specified minimum yield strength up to 100 ksi for elements and connections specified in Article 5.4.3.3.

The calculated force effects in the reinforcement at each section shall be developed on each side of that section by embedment length, hook, or mechanical device, or a combination thereof. Hooks and mechanical anchorages may be used in developing bars in tension only.

C5.10.8.1

The extension of the development and splice length provisions to normal weight concrete with design concrete compressive strengths up to 15.0 ksi for f'_c was originally based on the work presented in NCHRP Report 603 (Ramirez and Russell, 2008). The research addressed both uncoated and epoxy-coated reinforcement with bar sizes up to #11. The updated procedure described herein has been validated over a similar range of concrete strengths and reinforcement bar sizes (Bayrak and Zaborac, 2022).

5.10.8.1.2—Flexural Reinforcement

5.10.8.1.2a—General

Critical sections for development of reinforcement in flexural members shall be taken at points of maximum stress and at points within the span where bent or terminated tension reinforcement is no longer required to resist flexure.

Except at supports of simple spans and at the free ends of cantilevers, reinforcement shall be extended beyond the point at which it is no longer required to resist flexure for a distance not less than the greatest of the following:

- The effective depth of member, d ,
- 15 times the nominal diameter of bar, d_b , or
- $1/20$ of the clear span, L_{CLR} .

Continuing reinforcement shall extend not less than the development length, ℓ_d , specified in Article 5.10.8.2, beyond the point where bent or terminated tension reinforcement is no longer required to resist flexure.

C5.10.8.1.2a

Note the extension of bars D in Figure C5.10.8.1.2a-1 must also meet the requirements of Article 5.10.8.1.2b.

These provisions are a variation from ACI 318-19, requiring a slightly greater bar diameter limit (15 vs. 12) and including a ratio of the clear span (ACI has no span requirement). The reinforcement extension accounts for the possibility of higher than anticipated moments due to live load positioning, support settlements, or other causes.

Figure C5.10.8.1.2a-1—General Flexural Reinforcement Termination Requirements

No more than 50 percent of the reinforcement shall be terminated at any section, and adjacent bars shall not be terminated in the same section.

Tension reinforcement may also be developed by either bending across the web in which it lies and terminating it in a compression area and providing the development length ℓ_d to the design section, or by making it continuous with the reinforcement on the opposite face of the member.

As a maximum, every other bar in a section may be terminated.

Past editions of the Standard Specifications required that flexural reinforcement not be terminated in a tension zone, unless one of the following conditions was satisfied:

- The factored shear force at the cutoff point did not exceed two thirds of the factored shear resistance, including the shear strength provided by the shear reinforcement.

- Stirrup area in excess of that required for shear and torsion was provided along each terminated bar over a distance from the termination point not less than three-fourths the effective depth of the member. The excess stirrup area, A_v , was not less than $0.06 b_w s / f_y$. Spacing, s , did not exceed $0.125d / \beta_b$, where β_b was the ratio of the area of reinforcement cutoff to the total area of tension reinforcement at the section.
- For #11 bars and smaller, the continuing bars provided double the area required for flexure at the cutoff point, and the factored shear force did not exceed three fourths of the factored shear resistance.

These provisions are now supplemented by the provisions of Article 5.7, which account for the need to provide longitudinal reinforcement to react the horizontal component of inclined compression diagonals that contribute to shear resistance.

Supplementary anchorages may take the form of hooks or welding to anchor bars.

Supplementary anchorages shall be provided for tension reinforcement in flexural members where the reinforcement force is not directly proportional to factored moment as follows:

- sloped, stepped, or tapered footings;
- brackets;
- deep flexural members; or
- members in which tension reinforcement is not parallel to the compression face.

5.10.8.1.2b—Positive Moment Reinforcement

At least one-third the positive moment reinforcement in simple span members and one-fourth the positive moment reinforcement in continuous members shall extend along the same face of the member beyond the centerline of the support. In beams, such extension shall not be less than 6.0 in.

C5.10.8.1.2b

Past editions of the Standard Specifications required that at end supports and at points of inflection, positive moment tension reinforcement be limited to a diameter such that the development length, ℓ_d , determined for f_y by Article 5.10.8.2.1, satisfied Eq. C5.10.8.1.2b-1:

$$\ell_d \leq \frac{M_n}{V_u} + \ell_a \quad (\text{C5.10.8.1.2b-1})$$

where:

- M_n = nominal flexural resistance, assuming all positive moment tension reinforcement at the section to be stressed to the specified yield strength f_y (kip-in.)
- V_u = factored shear force at the section (kip)
- ℓ_a = embedment length beyond the center of a support or at a point of inflection; taken as the greater of the effective depth of the member and 12.0 d_b (in.)

Eq. C5.10.8.1.2b-1 does not have to be satisfied for reinforcement terminating beyond the centerline of end supports by either a standard hook or a mechanical anchorage at least equivalent to a standard hook.

The value M_n/V_u in Eq. C5.10.8.1.2b-1 was to be increased by 30 percent for the ends of the reinforcement located in an area where a reaction applies transverse compression to the face of the beam under consideration.

The intent of the 30 percent provision is illustrated in Figure C5.10.8.1.2b-1.

Note: The 1.3 factor is usable only if the reaction confines the ends of the reinforcement.

Figure C5.10.8.1.2b-1—End Confinement

These provisions are now supplemented by the provisions of Article 5.7, which account for the need to provide longitudinal reinforcement to resist the horizontal component of inclined compression diagonals that contribute to shear resistance.

Reinforcement with specified yield strengths in excess of 75.0 ksi may require longer extensions than required by this Article.

5.10.8.1.2c—Negative Moment Reinforcement

C5.10.8.1.2c

At least one-third of the total tension reinforcement provided for negative moment at a support shall have an embedment length beyond the point of inflection not less than the greatest of the following:

- The effective depth of member, d ,
- 12 times the nominal diameter of bar, d_b , or
- $1/16$ of the clear span, L_{CLR} .

Figure C5.10.8.1.2c-1—Negative Moment Reinforcement Termination Requirements

5.10.8.1.2d—Moment Resisting Joints

Flexural reinforcement in continuous, restrained, or cantilever members or in any member of a rigid frame shall be detailed to provide continuity of reinforcement at intersections with other members to develop the nominal moment resistance of the joint.

In Seismic Zones 3 and 4, joints shall be detailed to resist moments and shears resulting from horizontal loads through the joint.

5.10.8.2—Development of Reinforcement

Development lengths shall be calculated using the specified minimum yield strength of the reinforcement. Use of nonprestressed reinforcement with a specified minimum yield strength up to 100 ksi may be permitted for elements and connections specified in Article 5.4.3.3.

5.10.8.2.1—Deformed Bars and Deformed Wire in Tension

The provisions herein may be used for #18 bars and smaller, except as noted in Articles 5.10.8.2.4 and 5.10.8.2.7, in concrete with design compressive strengths specified in Article 5.1, including normal weight concrete up to 15.0 ksi. Transverse reinforcement consisting of at least #3 bars at 12.0-in. centers shall be provided along the required development length where the design concrete compressive strength is greater than 10.0 ksi.

C5.10.8.1.2d

Reinforcing details for developing continuity through joints are suggested in the *ACI Detailing Manual* (ACI SP-66, 2004).

C5.10.8.2

Prior to the tenth edition of the *AASHTO LRFD Bridge Design Specifications*, results of NCHRP Report 603 (Ramirez and Russell, 2008) were incorporated to include applications with compressive strengths of concrete used in design up to 15.0 ksi. The NCHRP 603 Report examined an extensive database of previous tests compiled by ACI Committee 408. Previous tests (Azizinamini et al.; 1993, 1999) had indicated that in the case of concrete with compressive strengths between 10.0 and 15.0 ksi, a minimum amount of transverse reinforcement was needed to ensure yielding of reinforcement splices of bars with less than 12.0 in. of concrete placed below them. Although NCHRP Report 603 recommends replacing the minimum transverse reinforcement with a development modification factor of 1.2, a conservative value of 1.3 was used. Furthermore, the bar size factor of 0.8 for #6 and smaller bars was removed to generalize application to concrete strength higher than 10.0 ksi. Research by Shahrooz et al. (2011) shows that tensile splice lengths and tensile development lengths for both straight bars and standard hooks calculated with ninth edition of the *AASHTO LRFD Bridge Design Specifications* were adequate for applications in Seismic Zone 1 for reinforcement with yield strengths up to 100 ksi combined with design concrete compressive strengths up to 15.0 ksi. The procedure described here has been shown to meet or exceed the performance of the ninth edition of the *AASHTO LRFD Bridge Design Specifications* over a similar range of concrete and reinforcement strengths without consideration for either modification factor (Zaborac and Bayrak, 2022).

C5.10.8.2.1

Prior to the tenth edition of the *AASHTO LRFD Bridge Design Specifications*, the extension of this Article to normal weight concrete with design concrete compressive strengths between 10.0 and 15.0 ksi was limited to #11 bars and smaller, and it was based on the work presented in NCHRP Report 603 (Ramirez and Russell, 2008). The procedure described here has been shown to meet or exceed the performance of ninth edition of the *AASHTO LRFD Bridge Design*

For straight bars having a specified minimum yield strength greater than 75.0 ksi, transverse reinforcement satisfying the requirements of Article 5.7.2.5 for beams and Article 5.10.4.3 for columns shall be provided over the required development length.

Specifications over a similar range of concrete and reinforcement strengths (Zaborac and Bayrak, 2022). Note that limited validation has been performed for bar sizes larger than #11, but procedure validation to-date suggests that Article 5.10.8.2.1 may be safely applied to bar sizes larger than #11. The requirement for minimum transverse reinforcement along the development length is based on research by Azizinamini et al. (1999). Transverse reinforcement used to satisfy the shear requirements may simultaneously satisfy this provision.

Confining reinforcement is not required in bridge slabs or decks.

5.10.8.2.1a—Tension Development Length

The modified tension development length, ℓ_d , shall not be less than the basic tension development length, ℓ_{db} , specified herein adjusted by the modification factor or factors specified in Articles 5.10.8.2.1b and 5.10.8.2.1c. The tension development length for nonheaded, straight bars and wires shall not be less than 12.0 in., except for development of shear reinforcement specified in Article 5.10.8.2.6.

The modified tension development length, ℓ_d , in in. shall be taken as:

$$\ell_d = \ell_{db} \times \lambda_{er} \times \lambda_{cf} \times \lambda_{rc} \quad (5.10.8.2.1a-1)$$

in which:

$$\ell_{db} = 0.17 d_b \left(\frac{\lambda_{er} f_y - \frac{F_h}{A_b}}{1.97 \lambda f'_c{}^{0.25}} \right)^2 \quad (5.10.8.2.1a-2)$$

where:

- ℓ_{db} = basic development length (in.)
- λ_{er} = reinforcement location factor
- λ_{cf} = coating factor
- λ_{rc} = reinforcement confinement factor
- d_b = nominal diameter of reinforcing bar or wire (in.)
- f_y = specified minimum yield strength of reinforcement (ksi)
- F_h = force developed by hooks or heads (kip)
- A_b = nominal area of reinforcing bar or wire (in.²)
- f'_c = compressive strength of concrete for use in design (ksi)
- λ_{er} = excess reinforcement factor
- λ = concrete density modification factor, as specified in Article 5.4.2.8

Modification factors shall be applied to the basic development length to account for the various effects

C5.10.8.2.1a

Eq. 5.10.8.2.1a-2 is the basic development length for the straight portion of bars developed in tension. It is primarily based on the partly cracked elastic model for bond behavior proposed by Tepfers (1979). The inclusion of the term F_h , which accounts for forces developed by hooks or heads, enables a unified approach to tension development length for straight bars, lap splices, hooked bars, and headed deformed bars. The denominator in Eq. 5.10.8.2.1a-2 represents the effective splitting strength of concrete in bond. The effective splitting strength of concrete in bond embedded in Eq. 5.10.8.2.1a-2 is based on a fourth-root dependency with concrete strength, and it includes the influence of (Zaborac and Bayrak, 2022). The fourth-root dependency on the compressive strength of concrete for use in design has been shown to be more accurate for bond than the typical square-root dependency used in many tension strength approximations (Zuo and Darwin, 2000) (Canbay and Froesch, 2005).

specified herein. They shall be taken equal to 1.0 unless they are specified to increase ℓ_d in Article 5.10.8.2.1b, or to decrease ℓ_d in Article 5.10.8.2.1c. For nonheaded straight bars and lap splices in tension, F_h shall be taken as zero.

5.10.8.2.1b—Modification Factors which Increase ℓ_d

The basic development length, ℓ_{db} , shall be modified by the following factor or factors, as applicable:

- For horizontal reinforcement, placed such that more than 12.0 in. of fresh concrete is cast below the reinforcement, $\lambda_{rf} = 1.3$.
- For epoxy-coated or zinc and epoxy dual-coated bars with cover less than $3d_b$ or with clear spacing between bars less than $6d_b$, $\lambda_{cf} = 1.5$.
- For epoxy-coated or zinc and epoxy dual-coated bars not covered above, epoxy-coated or zinc and epoxy dual-coated hooked bars designed with Article 5.10.8.2.4, and epoxy-coated or zinc and epoxy dual-coated headed bars designed with Article 5.10.8.2.7, $\lambda_{cf} = 1.2$.
- For uncoated or zinc-coated (galvanized) bars, $\lambda_{cf} = 1.0$.

The product $\lambda_{rf} \times \lambda_{cf}$ need not be taken greater than 1.7.

5.10.8.2.1c—Modification Factors which Decrease ℓ_d

The basic development length, ℓ_{db} , specified in Article 5.10.8.2.1a, modified by the factors specified in Article 5.10.8.2.1b, as appropriate, may be multiplied by the following factors:

- For reinforcement being developed in the length under consideration, λ_{rc} shall satisfy the following:

$$0.3 \leq \lambda_{rc} \leq 1.0 \quad (5.10.8.2.1c-1)$$

in which:

C5.10.8.2.1b

For horizontal reinforcement, placed such that no more than 12.0 in. of concrete is cast below the reinforcement, no modification factor is necessary or λ_{rf} could be said to be equal to 1.0. Prior to the tenth edition of the AASHTO LRFD Bridge Design Specifications, λ_{rf} was not required for the development of hooked bars. The accumulation of bleed water underneath top-cast bars has been documented to reduce bond strength in nonheaded, straight bars (ACI Committee 408, 2003). Eq. 5.10.8.2.1a-1, which is used to calculate the length of the straight portion of a hooked bar, is based on the behavior of a straight length of reinforcement subject to uniform average bond stresses. As a result, the influence of bar casting position is now required for hooked and headed bars. Note that the proportion of anchorage resisted by the hook, F_h , is not affected by the reinforcement location factor.

The coating factor, λ_{cf} , is limited to 1.2 for hooked and headed bars. The original coating factor for hooked bars was 1.2, and it was based on tests by Hamad et al. (1993) that did not satisfy the $3d_b$ clear cover and $6d_b$ clear spacing requirements. Therefore, it is unnecessary to use the larger value of 1.5. This limit also applies to headed bars based on recommendations by ACI 318-19.

C5.10.8.2.1c

The parameters, c_b and n , in Eqs. 5.10.8.2.1c-2 and 5.10.8.2.1c-3, as well as assumed crack locations, are shown in Figure C5.10.8.2.1c-1.

In tests to determine development lengths, splitting cracks have been observed to occur along the bars being developed as illustrated in Figure C5.10.8.2.1c-1. When the center-to-center spacing of the bars is greater than about twice the distance from the center of the bar to the concrete surface, splitting cracks occur between the bars and the concrete surface. When the center-to-center spacing of the bars is less than about twice the distance from the center of the bar to the concrete surface, splitting cracks occur between the bars along the plane of the bars being developed. The presence of bars

$$\lambda_{rc} = \frac{d_b c_b}{(c_b (1 - \beta_t) + 1.67 n_s k_{tr})^2} \quad (5.10.8.2.1c-2)$$

$$k_{tr} = \frac{A_{tr}}{(sn)} \quad (5.10.8.2.1c-3)$$

where:

c_b = the smaller of the distance from center of bar or wire being developed to the nearest concrete surface and one-half the center-to-center spacing of the bars or wires being developed (in.)

β_r = ratio of unfactored compressive stress due to permanent loads (taken as a negative value) transverse to the plane of splitting to the modulus of rupture, as determined by Article 5.4.2.6 ($-1 \leq \beta_r \leq 0$)

$$n_s = \text{modular ratio, } E_s/E_c$$
 k_{tr} = transverse reinforcement index

A_{tr} = total cross-sectional area of all transverse reinforcement which is within the spacing s and which crosses the potential plane of splitting through the reinforcement being developed (in.²)

s = maximum center-to-center spacing of transverse reinforcement within ℓ_d (in.)

n = number of bars or wires developed along plane of splitting

- Where anchorage or development for the full yield strength of reinforcement is not required, or where reinforcement in flexural members is in excess of that required by analysis:

$$\lambda_{er} = \frac{\text{Required } A_s}{\text{Provided } A_s} \quad (5.10.8.2.1c-4)$$

crossing the plane of splitting, as denoted by A_{tr} , controls these splitting cracks and results in shorter development lengths.

In any member, A_{tr} may be taken conservatively as zero in Eq. 5.10.8.2.1c-3.

The ratio of unfactored compressive stress due to permanent loads transverse to the plane of splitting to the effective concrete tension strength, β_n , accounts for the beneficial effects of clamping stresses that may exist perpendicular to the plane of splitting. Transverse compressive stresses act as confinement that delay the onset of splitting failures (*fib*, 2013). For example, concentrated stresses above or below a load/support can be assumed to enhance the bond strength over the length of reinforcement that passes through the load/support plate length (*fib*, 2013). It could be conservatively considered as zero in Eq. 5.10.8.2.1c-2 for new design. The concrete modulus of rupture is estimated with Article 5.4.2.6. While this overestimates the concrete splitting strength, it is conservative for use in Eq. 5.10.8.2.1c-2 because the overestimation of splitting strength reduces the calculated β_n .

In Eq. 5.10.8.2.1a-2, the excess reinforcement factor modifies the yield stress instead of the development length based on the following relationship: $f_s \times (\text{Provided } A_s) = f_y \times (\text{Required } A_s)$.

Figure C5.10.8.2.1c-1—Parameters for Determining Development Length Modifier, λ_{rc}

5.10.8.2.2—Deformed Bars in Compression

5.10.8.2.2a—Compressive Development Length

The modified development length, ℓ_d , for deformed bars in compression shall not be less than either the basic development length, ℓ_{db} , specified herein modified by the applicable modification factors specified in Article 5.10.8.2.2b, or 8.0 in.

The modified compressive development length, ℓ_{db} , for deformed bars shall be taken as:

$$\ell_d = \ell_{db} \frac{\lambda_{er} \lambda_{rc}}{\lambda} \quad (5.10.8.2.2a-1)$$

The basic development length shall be larger than the greater of the following:

Report 603 recommends a minimum amount of transverse reinforcement consisting of at least #3 U bars at $3d_b$ spacing to improve the bond strength of #11 and larger bars in tension anchored by means of standard hooks. Similar to the provisions of ACI 318-19, hooks are not considered effective in developing bars in compression.

5.10.8.2.4a—Hooked Bar Development Length

The modified development length, ℓ_{dh} , in in., for deformed bars in tension terminating in a standard hook specified in Article 5.10.2.1 shall be taken as:

$$\ell_{dh} = \ell_d + R + \frac{d_b}{2} \quad (5.10.8.2.4a-1)$$

but not less than the greater of the following:

- 8.0 bar diameters; and
- 6.0 in.

where:

ℓ_d = modified tension development length, specified in Article 5.10.8.2.1 (in.)
 R = radius of the hook measured from the center of the bend to the centroid of the bar (in.)
 d_b = nominal diameter of reinforcing bar or wire (in.)

To calculate the modified development length of a standard hook in tension, the force developed by a standard hook, F_h , in Eqs. 5.10.8.2.1a-1 and 5.10.8.2.1a-2 shall be taken as:

$$F_h = d_b R v f'_c \quad (5.10.8.2.4a-2)$$

where:

v = concrete efficiency factor for a CTT node, specified in Table 5.8.2.5.3a-1
 f'_c = concrete design compressive strength (ksi)

5.10.8.2.4b—Hooked-Bar Tie Requirements

It is permissible to conservatively take k_{tr} as zero in Eq. 5.10.8.2.1c-2 and reduce ℓ_{dh} calculated in Eq. 5.10.8.2.4a-1 by 20 percent provided any of the three detailing requirements in Figure C5.10.8.2.4b-1 are met. However, for bars being developed by a standard hook at discontinuous ends of members with both side cover and top or bottom cover less than 2.5 in., the hooked bar shall be enclosed within ties or stirrups spaced along the full development length, ℓ_{dh} , not greater than $3d_b$ as shown in Figure 5.10.8.2.4b-1. The

C5.10.8.2.4a

Figure C5.10.8.2.4a-1—Hooked Bar Details for Development of Standard Hooks (ACI Committee 318, 2011)

C5.10.8.2.4b

The provisions in this article are adapted from ACI 318-19.

Confinement of hooked bars by stirrups perpendicular and parallel to the bar being developed is illustrated in Figure C5.10.8.2.4b-1. The influence of parallel tie reinforcement is conservatively neglected in Eq. 5.10.8.2.1a-1; however, research has shown that it is an effective method for improving the performance of hooked bars (Sperry et al. 2017). This provision does not apply for hooked bars at discontinuous ends of slabs

transverse reinforcement index, k_{tr} , specified in Article 5.10.8.2.1c shall be taken as zero in this case and ℓ_{dh} shall not be reduced.

For normal weight concrete with design concrete compressive strengths between 10.0 and 15.0 ksi, the development length of the hooked bars shall be enclosed with #3 bars or larger ties or stirrups along the full development, ℓ_{dh} , at a spacing not greater than $3d_b$. A minimum of three ties or stirrups shall be provided.

Figure 5.10.8.2.4b-1—Hooked-Bar Tie Requirements

where confinement is provided by the slab on both sides, perpendicular to the plane of the hook.

The concrete efficiency factor for a CTT node specified in Table 5.8.2.5.3a-1 is appropriate, regardless of the percentage of reinforcement confining the bar, due to low strain values associated with tensile failure of concrete around the bar being anchored and based on the experimental validation reported by Zaborac and Bayrak (2022).

There are no publicly available test results for #14 and #18 bars. As a result, Article 5.10.8.2.4 is limited to #11 bars and smaller based on experimental validation (Zaborac and Bayrak 2022). However, ACI 318-19 doubles the calculated hooked bar development length for #14 and #18 bars, regardless of the provided confinement reinforcement and clear cover. Based on this ACI 318-19 guidance, it may be possible to develop a conservative estimate of the hooked bar development length for #14 and #18 bars by doubling the value of ℓ_{dh} calculated with Eq. 5.10.8.2.4a-1. Based on CRSI guidance, to address worker safety concerns, bars larger than #14 with Grade 75 or higher should not be bent.

Figure C5.10.8.2.4b-1—Confinement of Hooked Bars by Stirrups

5.10.8.2.5—Welded Wire Reinforcement

For applications other than shear reinforcement, the modified development length, ℓ_d , in inches, for deformed or plain welded wire reinforcement shall be determined as the basic development length, ℓ_{db} , adjusted by the modification factors specified in Eq. 5.10.8.2.5-1, but shall not be taken as less than the greatest of the following:

Deformed welded wire reinforcement:

- The distance that will include embedment of one cross wire with the cross wire not less than 2.0 in. from the point of critical section; or

- 8.0 in.

Plain welded wire reinforcement:

- The distance between two cross wires plus the distance from the critical section to the closer cross wire, where the closer cross wire is not less than 2.0 in. from the point of critical section; or

- 6.0 in.

The modified development length, ℓ_d , in inches, of deformed or plain welded wire reinforcement, measured from the point of critical section to the end of wire, shall be taken as:

$$\ell_d = \ell_{db} \times \left(\frac{\lambda_{er}}{\lambda} \right) \quad (5.10.8.2.5-1)$$

The basic development length, ℓ_{db} , for deformed welded wire reinforcement, shall be taken as the greater of:

$$\ell_{db} \geq 0.95d_b \frac{f_y - 20.0}{\sqrt{f'_c}} \quad (5.10.8.2.5-2)$$

$$\ell_{db} \geq 6.30 \frac{A_w f_y}{s_w \sqrt{f'_c}} \quad (5.10.8.2.5-3)$$

The basic development length, ℓ_{db} , for plain welded wire reinforcement, shall be taken as:

$$\ell_{db} = 8.50 \frac{A_w f_y}{s_w \sqrt{f'_c}} \quad (5.10.8.2.5-4)$$

where:

λ_{er} = excess reinforcement factor, as specified in Article 5.10.8.2.1c

λ = concrete density modification factor, as specified in Article 5.4.2.8

C5.10.8.2.5

Figure C5.10.8.2.5-1 shows the development requirements for deformed welded wire reinforcement within one cross wire within the development length. ASTM A1064/A1064M for deformed welded wire reinforcement requires the same strength of the weld as required for plain welded wire reinforcement. Some of the development is assigned to welds and some assigned to the length of deformed wire. For deformed welded wire reinforcement made with smaller wires, an embedment of at least one cross wire 2.0 in. or more beyond the point of critical section is adequate to develop the full yield strength of the anchored wires. However, for deformed welded wire reinforcement made with larger closely spaced wires, a longer embedment is required and a minimum development length is provided for this reinforcement.

Figure C5.10.8.2.5-1—Development of Deformed Welded Wire Reinforcement (adapted from ACI 318-14, courtesy of ACI)

Figure C5.10.8.2.5-2 shows the development requirements for plain welded wire reinforcement with development primarily dependent on the location of cross wires. For plain welded wire reinforcement made with the smaller wires, an embedment of at least two cross wires, 2.0 in. or more beyond the point of critical section is adequate to develop the full yield strength of the anchored wires. However, for plain welded wire reinforcement made with larger closely spaced wires, a longer embedment is required and a minimum development length is provided for this reinforcement.

Figure C5.10.8.2.5-2—Development of Plain Welded Wire Reinforcement (adapted from ACI 318-14, courtesy of ACI)

- d_b = nominal diameter of reinforcing bar or wire (in.)
 f_y = specified minimum yield strength of reinforcement (ksi)
 f'_c = concrete design compressive strength for use in design specified in Article 5.1, including normal weight concrete up to 15.0 ksi (ksi)
 A_w = area of individual wire to be developed or spliced (in.²)
 s_w = spacing of wires to be developed or spliced (in.)

The basic development length of deformed welded wire reinforcement, with no cross wires within the development length, shall be determined as for deformed wire in accordance with Article 5.10.8.2.1a.

For plain welded wire reinforcement development, use of two cross wires is required.

The development of shear reinforcement shall be taken as specified in Article 5.10.8.2.6.

5.10.8.2.6—Shear Reinforcement

5.10.8.2.6a—General

Stirrup reinforcement in concrete pipe shall satisfy the provisions of Article 12.10.4.2.7 and shall not be required to satisfy the provisions herein.

Shear reinforcement shall be located as close to the surfaces of members as cover requirements and proximity of other reinforcement permit.

Between anchored ends, each bend in the continuous portion of a simple U-stirrup or multiple U-stirrup shall enclose a longitudinal bar.

Longitudinal bars bent to act as transverse reinforcement, if extended into a region of tension, shall be continuous with the longitudinal reinforcement and, if extended into a region of compression, shall be anchored beyond the mid-depth, $h/2$, as specified for development length for that part of the stress in the reinforcement required to satisfy Eq. 5.7.3.3-5.

5.10.8.2.6b—Anchorage of Deformed Reinforcement

Ends of single-leg, simple U-, or multiple U-stirrups shall be anchored as follows:

- For #5 bar and D31 wire, and smaller—A standard hook around longitudinal reinforcement, and
- For #6, #7 and #8—A standard stirrup hook around a longitudinal bar, plus one embedment length between midheight of the member and the outside end of the hook, ℓ_e shall satisfy:

$$\ell_e \geq \frac{0.44 d_b f_y}{\lambda \sqrt{f'_c}} \quad (5.10.8.2.6b-1)$$

where:

- d_b = nominal diameter of reinforcing bar or wire (in.)
- f_y = specified minimum yield strength of reinforcement (ksi)
- λ = concrete density modification factor, as specified in Article 5.4.2.8
- f'_c = concrete design compressive strength for use in design specified in Article 5.1, including normal weight concrete up to 15.0 ksi (ksi)

5.10.8.2.6c—Anchorage of Wire Fabric Reinforcement

C5.10.8.2.6c

Each leg of welded plain wire reinforcement forming simple U-stirrups shall be anchored by:

- Two longitudinal wires spaced at 2.0 in. along the member at the top of the U; or
- One longitudinal wire located not more than $d/4$ from the compression face and a second wire closer to the compression face and spaced not less than 2.0 in. from the first wire. The second wire may be located on the stirrup leg beyond a bend or on a bend with an inside diameter of bend not less than $8d_b$.

For each end of a single-leg stirrup of welded plain or deformed wire reinforcement, two longitudinal wires at a minimum spacing of 2.0 in. and with the inner wire at not less than $d/4$ or 2.0 in. from mid-depth of member shall be provided. The outer longitudinal wire at tension face shall not be farther from the face than the portion of primary flexural reinforcement closest to the face.

Figure C5.10.8.2.6c-1—Anchorage of Single-Leg Welded Wire Reinforcement Shear Reinforcement, ACI 318-14

5.10.8.2.6d—Closed Stirrups

Pairs of U-stirrups that are placed to form a closed unit shall be considered properly anchored and spliced where length of laps is not less than $1.3\ell_d$, where ℓ_d in this case is the development length for bars in tension.

In members not less than 18.0 in. deep, closed stirrup splices in stirrup legs extending the full available depth of the member, and with the tension force resulting from factored loads, $A_b f_y$, not exceeding 9.0 kips per leg, may be considered adequate.

Transverse torsion reinforcement shall be made fully continuous and shall be anchored by 135-degree standard hooks around longitudinal reinforcement.

5.10.8.2.7—Headed Deformed Bar Development Length

The provisions herein may be used for headed #11 bars or smaller with a net bearing area of head equal to or larger than four times the bar area in normal weight concrete with a compressive strength of concrete for use in design up to 15.0 ksi and lightweight concrete up to 10.0 ksi. Headed bars designed with these provisions shall conform to ASTM A970/A970M and satisfy requirements for Class HA head dimensions (Annex 1 of ASTM A970/A970M).

Headed deformed bars designed with the provisions herein shall have a clear cover to the heads not less than two times the bar diameter and a center-to-center spacing not less than three times the bar diameter. The head shall be considered for satisfying minimum cover requirements in Table 5.10.1-1 and the minimum clear spacing requirements of Article 5.10.3.1.

The modified development length, l_{dt} , in in. for headed deformed bars in tension shall be taken as:

$$l_{dt} = l_d$$

but not less than the greater of the following:

- 8.0 bar diameters; and
- 6.0 in.

where:

l_d = modified tension development length specified in Article 5.10.8.2.1 (in.)

To calculate the modified development length, l_{dt} , of a headed deformed bar in tension, the force developed by a head, F_h , in Eqs. 5.10.8.2.1a-1 and 5.10.8.2.1a-2, shall be taken as:

$$F_h = 0.5A_{ht}v_f'c' \quad (5.10.8.2.7-1)$$

where:

A_{ht} = net area of the head that bears on concrete
 v = concrete efficiency factor for a CTT node, specified in Table 5.8.2.5.3a-1

For headed #11 bars or smaller within beam-column joints, it is permissible to reduce the development length calculated using Eq. 5.10.8.2.1a-1 by 20 percent if a total area of parallel tie reinforcement equal to 30 percent of the total area of headed bars is provided within $8d_b$ of the centerline of the headed bar, between the headed bar and the center of the beam-column joint.

C5.10.8.2.7

Eqs. 5.10.8.2.1a-1 and 5.10.8.2.7-1 have been validated for headed deformed bar sizes up to #11 with net bearing area of head equal to or larger than four times the bar area in normal weight concrete with a compressive strength of concrete for use in design up to 15.0 ksi by Zaborac and Bayrak (2022). The *fib Model Code 2010* (fib, 2012) contains a similar general formulation, and it does not restrict the use of lightweight concrete in combination with headed bar anchorage. Eq. 5.10.8.2.1a-2 accounts for the influence of lightweight concrete by reducing the effective concrete tension strength in bond with the concrete density modification factor. Therefore, the use of lightweight concrete is allowed by these provisions, and it is subjected to the same concrete strength limits as nonheaded straight bars, lap splices in tension, and hooked bars.

The minimum spacing, cover, and development length requirements are based on the requirements of ACI 318-19. The influence of parallel tie reinforcement is conservatively neglected in Eq. 5.10.8.2.1a-1; however, research has shown that it is an effective method for improving the performance of headed deformed bars (Ghimere et al., 2019). The reduction permitted for parallel tie reinforcement within beam-column joints is a conservative interpretation of the ACI 318-19 provisions, and it is analogous to the reduction described in Article 5.10.8.2.4b for hooked bars. The influence of confinement reinforcement can be investigated with the strut-and-tie modeling procedure in Article 5.8 for most typical cases. If a headed bar does not comply with Article 5.10.8.2.7, then Article 5.10.8.3 or Article 5.13 should be considered.

The concrete efficiency factor for a CTT node specified in Table 5.8.2.5.3a-1 is appropriate, regardless of the percentage of reinforcement confining the bar, due to low strain values associated with tensile failure of concrete around the bar being anchored and based on the experimental validation reported by Zaborac and Bayrak (2022).

- one-fifth the required lap splice length; or
- 6.0 in.,

the spacing of the shaft transverse reinforcement in the splice zone shall meet the requirements of the following equation:

$$S_{\max} = \frac{2\pi A_{sp} f_{ytr} \ell_s}{k A_t f_{uf}} \quad (5.10.8.4.2a-1)$$

where:

$$S_{\max} = \text{spacing of transverse shaft reinforcement (in.)}$$
$$A_{sp} = \text{area of shaft spiral or hoop (in.}^2\text{)}$$

f_{ytr} = specified minimum yield strength of shaft
transverse reinforcement (ksi)

ℓ_s = required tension lap splice length of the column longitudinal reinforcement (in.)

k = factor representing the ratio of column tensile reinforcement to total column reinforcement at the nominal resistance

$$A_\ell = \begin{array}{l} \text{area of longitudinal column reinforcement} \\ (\text{in.}^2) \end{array}$$

f_{ut} = specified minimum tensile strength of column longitudinal reinforcement (ksi), 90.0 ksi for ASTM A615/A615M and 80.0 ksi for ASTM A706/A706M

5.10.8.4.2b—Mechanical Connections

The resistance of a full-mechanical connection shall not be less than 125 percent of the specified yield strength of the bar in tension or compression, as required. The total slip of the bar within the splice sleeve of the connector after loading in tension to 30.0 ksi and relaxing to 3.0 ksi shall not exceed the following measured displacements between gauge points clear of the splice sleeve:

- For bar sizes up to #14..... 0.01 in.
- For #18 bars..... 0.03 in.

5.10.8.4.2c—Welded Splices

Welding for welded splices shall conform to the current edition of AWS D1.4, *Structural Welding Code—Reinforcing Steel*.

A full-welded splice shall be required to develop, in tension, at least 125 percent of the specified yield strength of the bar.

No welded splices shall be used in decks.

5.10.8.4.3—Splices of Reinforcement in Tension

The provisions herein may be used for #11 bars or smaller in concrete with design compressive strengths specified in Article 5.1, including normal weight

C5.10.8.4.3

The tension development length, ℓ_d , used as a basis for calculating splice lengths should include all of the modification factors specified in Article 5.10.8.2.

concrete up to 15.0 ksi. Transverse reinforcement consisting of at least #3 bars at 12.0-in. centers shall be provided along the required splice length where the design concrete compressive strength is greater than 10.0 ksi. A minimum of three bars shall be provided.

5.10.8.4.3a—Lap Splices in Tension

The minimum length of lap for tension lap splices shall be as required for Class A or B lap splice, but not less than 12.0 in., where:

Class A splice.....	$1.0\ell_d$
Class B splice.....	$1.3\ell_d$

The tension development length, ℓ_d , for the specified yield strength shall be taken in accordance with Article 5.10.8.2.1a.

Except as specified herein, lap splices of deformed bars and deformed wire in tension shall be Class B lap splices. Class A lap splices may be used where:

- the area of reinforcement provided is at least twice that required by analysis over the entire length of the lap splice; and
- one-half or less of the total reinforcement is spliced within the required lap splice length.

For splices having $f_y > 75.0$ ksi, transverse reinforcement satisfying the requirements of Article 5.7.2.5 in beams and Article 5.10.4.3 in columns shall be provided over the required lap splice length.

5.10.8.4.3b—Mechanical Connections or Welded Splices in Tension

Mechanical connections or welded tension splices, used where the area of reinforcement provided is less than twice that required, shall meet the requirements for full-mechanical connections or full-welded splices.

Mechanical connections or welded splices, used where the area of reinforcement provided is at least twice that required by analysis and where the splices are staggered at least 24.0 in., may be designed to develop not less than either twice the tensile force effect in the bar at the section or half the minimum specified yield strength of the reinforcement.

The extension of this Article to normal weight concrete with design concrete compressive strengths between 10.0 and 15.0 ksi is limited to #11 bars and smaller based on the work presented in NCHRP Report 603 (Ramirez and Russell, 2008). The requirement for minimum transverse reinforcement along the splice length is based on research by Azizinamini et al. (1999). Transverse reinforcement used to satisfy the shear requirements may simultaneously satisfy this provision.

C5.10.8.4.3a

Research by Shahrooz et al. (2011) verified these provisions for applications in Seismic Zone I for reinforcement with specified minimum yield strengths up to 100 ksi combined with design concrete compressive strengths up to 15.0 ksi. See Article C5.4.3.3 for further information.

Tension lap splices were evaluated under NCHRP Report 603. Splices of bars in compression were not part of the experimental component of the research. Class C lap splices were eliminated based on the modifications to development length provisions.

C5.10.8.4.3b

In determining the tensile force effect developed at each section, spliced reinforcement may be considered to resist the specified splice strength. Unspliced reinforcement may be considered to resist the fraction of f_y defined by the ratio of the shorter actual development length to the development length, ℓ_d , required to develop the specified yield strength f_y .

5.10.8.4.4—Splices in Tie Members

Splices of reinforcement in tie members shall be made only with either full-welded splices or full-mechanical connections. Splices in adjacent bars shall be staggered not less than 30.0 in. apart.

C5.10.8.4.4

A tie member is assumed to have:

- an axial tensile force sufficient to create tension over the cross-section, and
- a level of stress in the reinforcement such that every bar is fully effective.

Examples of members that may be classified as tension ties are arch ties, hangers carrying load to an overhead supporting structure, and main tension components in a truss.

5.10.8.4.5—Splices of Bars in Compression

5.10.8.4.5a—Lap Splices in Compression

C5.10.8.4.5a

The length of lap, ℓ_c , for compression lap splices shall not be less than both 12.0 in. and whichever of the following is appropriate:

- If $f_y \leq 60.0$ ksi then:

$$\ell_c = 0.5mf_yd_b \quad (5.10.8.4.5a-1)$$

- If $f_y > 60.0$ ksi then:

$$\ell_c = m(0.9f_v - 24.0)d_b \quad (5.10.8.4.5a-2)$$

in which:

- Where the compressive strength of concrete used in design, f'_c , is less than 3.0 ksi $m = 1.33$
- Where ties or hoops with closure made using a lap splice along the splice have an effective area not less than 0.15 percent of the product of the thickness of the compression component times the tie or hoop spacing $m = 0.83$
- With spirals or hoops with closure made using a full-welded splice, a full-mechanical coupler, or by overlapping with hooks around longitudinal reinforcement $m = 0.75$
- In all other cases $m = 1.0$

The effective area of the ties is the area of the legs perpendicular to the thickness of the component, as seen in cross-section. The effective area of the hoop is the area of the hoop reinforcement perpendicular to the plane bisecting the cross-section of the member.

where:

$$f_y = \text{specified yield strength of reinforcing bars (ksi)}$$
$$d_b = \text{nominal diameter of reinforcing bar (in.)}$$

Where bars of different size are lap spliced in compression, the splice length shall not be less than the development length of the larger bar or the splice length of smaller bar. Bar sizes #14 and #18 may be lap spliced to #11 and smaller bars.

5.10.8.4.5b—Mechanical Connections or Welded Splices in Compression

Mechanical connections or welded splices used in compression shall satisfy the requirements for full-mechanical connections or full-welded splices as specified in Articles 5.10.8.4.2b and 5.10.8.4.2c, respectively.

5.10.8.4.5c—End-Bearing Splices

In bars required for compression only, the compressive force may be transmitted by bearing on square-cut ends held in concentric contact by a suitable device. End-bearing splices shall be used only in members confined by spirals, hoops, ties, and closed stirrups.

The end-bearing splices shall be staggered, or continuing bars shall be provided at splice locations. The continuing bars in each face of the member shall have a factored tensile resistance not less than $0.25f_y$ times the area of the reinforcement in that face.

5.10.8.5—Splices of Welded Wire Reinforcement

5.10.8.5.1—Splices of Deformed Welded Wire Reinforcement in Tension

When measured between the ends of each reinforcement sheet, the length of lap for lap splices of deformed welded wire reinforcement with cross wires within the lap length shall not be less than the greater of the following:

- $1.3\ell_d$; or
- 8.0 in.

The overlap measured between the outermost cross wires of each reinforcement sheet shall not be less than 2.0 in.

Lap splices of deformed welded wire reinforcement with no cross wires within the lap splice length shall be determined as for deformed wire in accordance with the provisions of Article 5.10.8.4.3a.

C5.10.8.5.1

Splice provisions for deformed welded wire reinforcement are based on available tests (ACI 318-14). Lap splices for deformed welded wire reinforcement meeting the requirements of this provision are illustrated in Figure C5.10.8.5.1-1. If no cross wires are within the lap length, the provision for deformed wire apply.

Figure C5.10.8.5.1-1—Lap Splices of Deformed Welded Wire Reinforcement (adapted from ACI 318-14, courtesy of ACI)

5.10.8.5.2—Splices of Plain Welded Wire Reinforcement in Tension

C5.10.8.5.2

Where the area of reinforcement provided is less than twice that required at the splice location, the length

The strength of lap splices of plain welded wire reinforcement is dependent primarily on the anchorage

of overlap measured between the outermost cross wires of each reinforcement sheet shall not be less than the greatest of the following:

- The sum of one spacing of cross wires plus 2.0 in.;
- $1.5\ell_d$; or
- 6.0 in.

Where the area of reinforcement provided is at least twice that required at the splice location, the length of overlap measured between the outermost cross wires of each reinforcement sheet shall not be less than the greater of the following:

- $1.5\ell_d$; or
- 2.0 in.

where:

ℓ_d = development length computed in Eq. 5.10.8.2.5-1 (in.)

obtained from the cross wires rather than on the length of wire in the splice. For this reason, the lap is specified in terms of overlap of cross wires (in inches) rather than in wire diameters or length. The 2.0 in. additional lap required is to provide adequate overlap of the cross wires and to provide space for satisfactory consolidation of the concrete between cross wires. Research (ACI 318-14) has shown an increased splice length is required when welded wire reinforcement of large, closely spaced wires is lapped and, as a consequence, additional splice length requirements are provided for this reinforcement in addition to an absolute minimum of 6.0 in. Splice requirements are illustrated in Figure C5.10.8.5.2-1.

Where the area of reinforcement provided is at least twice that required at the splice location, the lap splice for plain welded wire reinforcement is illustrated in Figure C5.10.8.5.2-2.

Figure C5.10.8.5.2-1—Lap Splices of Plain Welded Wire Reinforcement where $(\text{Provided } A_s)/(\text{Required } A_s) < 2$ (adapted from ACI 318-14, Courtesy of ACI)

Figure C5.10.8.5.2-2—Lap Splices of Plain Welded Wire Reinforcement where $(\text{Provided } A_s)/(\text{Required } A_s) \geq 2$ (adapted from ACI 318-14, Courtesy of ACI)

5.11—SEISMIC DESIGN AND DETAILS

5.11.1—General

The provisions of these Articles shall apply only to the extreme event limit state.

In addition to the other requirements specified in Article 5.10, reinforcement shall also conform to the seismic resistance provisions specified herein.

Displacement requirements specified in Article 4.7.4.4 or longitudinal restrainers specified in Article 3.10.9.5 shall apply.

The provisions for piles in Article 5.12.9 shall apply unless they conflict with the provisions for Seismic Zones 2, 3, and 4 specified herein.

C5.11.1

These specifications have their origins in the work by the Applied Technology Council in 1979–1980. As such they prescribe force based design. Insights gained from the response of bridges to earthquakes since that time have provided new insights into the behavior of concrete details under seismic loads. The California Department of Transportation initiated a number of research projects that have produced information that is useful for both the design of new structures and the retrofitting of existing structures. Much of this information has formed the basis of recent provisions

The use of reinforcement with specified minimum yield strengths of less than or equal to 100 ksi may be used in elements and connections specified in Article 5.4.3.3, where permitted by specific Articles.

Bridges located in Seismic Zone 2 shall satisfy the requirements in Article 5.11.3. Bridges located in Seismic Zones 3 and 4 shall satisfy the requirements specified in Article 5.11.4.

5.11.2—Seismic Zone 1

For bridges in Seismic Zone 1 where the acceleration coefficient, S_{D1} , specified in Article 3.10.6, is less than 0.10, no consideration of seismic forces shall be required for the design of structural components, except that the design of the connection of the superstructure to the substructure shall be as specified in Article 3.10.9.2.

For bridges in Seismic Zone 1 where the acceleration coefficient, S_{D1} , is greater than or equal to 0.10 but less than or equal to 0.15, no consideration of seismic forces shall be required for the design of structural components, including concrete piles, except that:

- The design of the connection of the superstructure to the substructure shall be as specified in Article 3.10.9.2.
- The transverse reinforcement requirements at potential plastic hinge regions in columns and pile bents shall be as specified in Articles 5.11.4.1.3, 5.11.4.1.4, and 5.11.4.1.5.
- The spacing or pitch of the transverse reinforcement over the length of lap-spliced longitudinal column or pile bent reinforcement shall not exceed the lesser of one quarter of the minimum member dimension or 4.0 in.

Lap splices of reinforcement may be used in Seismic Zone 1.

5.11.3—Seismic Zone 2

5.11.3.1—General

The requirements of Article 5.11.4 shall be taken to apply to bridges in Seismic Zone 2 except that the area of longitudinal reinforcement shall not be less than 0.01 or more than 0.06 times the gross cross-section area, A_g .

published by NCHRP (2002, 2006), MCEER/ATC (2003), FHWA (2006) and the *AASHTO Guide Specifications for LRFD Seismic Bridge Design* (2023).

This new information relates to all facets of seismic engineering, including design spectra, analytical techniques, and design details. Bridge designers working in Seismic Zones 2, 3, and 4 are encouraged to avail themselves of current research reports and other literature to augment these Specifications, including AASHTO (2023), which is displacement-based rather than force-based and has more explicit requirements for ductility and displacement capacity in higher seismic regions than is provided by these Specifications.

C5.11.2

These requirements for Zone 1 are a departure from those in the previous edition of these specifications. These changes are necessary because the return period of the design event has been increased from 500 to 1000 years, and the Zone Boundaries (Table 3.10.6-1) have been increased accordingly. The high end of the new Zone 1 ($0.10 < S_{D1} < 0.15$) overlaps with the low end of Zone 2 as it was specified before the fifth edition of these specifications. Since performance expectations have not changed with increasing return period, the minimum requirements for bridges in the high end of Zone 1 should therefore be the same as those for the previous Zone 2. Requirements for the remainder of Zone 1 ($S_{D1} < 0.10$) are unchanged.

Lap splices are permitted in Seismic Zone 1 on the basis that they were permitted in Zone 2 as it was specified before the fifth edition of the *AASHTO LRFD Bridge Design Specifications*.

C5.11.3.1

Bridges in Seismic Zone 2 have a reasonable probability of being subjected to seismic forces that will cause yielding of the columns. Thus, it is deemed necessary that columns have some ductility capacity, although it is recognized that the ductility demand will not be as great as for columns of bridges in Seismic Zones 3

and 4. Nevertheless, all of the requirements for Zones 3 and 4 shall apply to bridges in Zone 2, with exception of the upper limit on reinforcement. This is a departure from the requirements in the fifth edition of these Specifications (2010), in which selected requirements in Zones 3 and 4 were required for Zone 2. Satisfying all of the requirements, with one exception, is deemed necessary because the upper boundary for Zone 2 in the current edition is significantly higher than in the 2010 edition.

5.11.3.2—Concrete Piles

5.11.3.2.1—General

Piles for structures in Zone 2 may be used to resist both axial and lateral loads. The minimum depth of embedment and axial and lateral pile resistances required for seismic loads shall be determined by means of design criteria established by site-specific geological and geotechnical investigations.

Concrete piles shall be anchored to the pile footing or cap by either embedment of reinforcement or anchorages to develop uplift forces. The embedment length shall not be less than the development length required for the reinforcement specified in Article 5.10.8.2.

Concrete-filled pipe piles shall be anchored with steel dowels as specified in Article 5.12.9.1, with a minimum steel ratio of 0.01. Dowels shall be embedded as required for concrete piles. Timber and steel piles, including unfilled pipe piles, shall be provided with anchoring devices to develop any uplift forces. The uplift force shall not be taken to be less than 10 percent of the factored axial compressive resistance of the pile.

5.11.3.2.2—Cast-in-Place Piles

For cast-in-place piles, longitudinal steel shall be provided in the upper end of the pile for a length not less than the greater of the following:

- one-third of the pile length; or
- 8.0 ft,

with a minimum steel ratio of 0.005 provided by at least four bars. For piles less than 24.0 in. in diameter, spiral reinforcement or equivalent ties of not less than #3 bars shall be provided at pitch not exceeding 9.0 in., except that the pitch shall not exceed 4.0 in. within a length below the pile cap reinforcement of not less than greater of the following:

- 2.0 ft; or
- 1.5 pile diameters.

C5.11.3.2.2

Cast-in-place concrete pilings may only have been vibrated directly beneath the pile cap, or in the uppermost sections. Where concrete is not vibrated, nondestructive tests in the state of California have shown that voids and rock pockets form when adhering to maximum confinement steel spacing limitations from some seismic recommendations. Concrete does not readily flow through the resulting clear distances between bar reinforcing, weakening the concrete section, and compromising the bending resistance to lateral seismic loads. Instead of reduced bar spacing, bar diameters should be increased, which results in larger openings between the parallel longitudinal and transverse reinforcement.

5.11.3.2.3—Precast Reinforced Piles

For precast reinforced piles, the longitudinal steel shall not be less than 1 percent of the cross-sectional area and provided by not less than four bars. Transverse reinforcement of not less than #3 bars shall be provided at a pitch or spacing not exceeding 9.0 in., except that a 3.0 in. pitch or spacing shall be used within a confinement length not less than 2.0 ft or 1.5 pile diameters below the pile cap reinforcement.

5.11.3.2.4—Precast Prestressed Piles

For precast prestressed piles, the ties shall conform to the requirements of precast piles, as specified in Article 5.11.3.2.3.

5.11.4—Seismic Zones 3 and 4

5.11.4.1—Column Requirements

For the purpose of this Article, a vertical support shall be considered to be a column if the ratio of the clear height to the maximum plan dimensions of the support is not less than 2.5. For a flared column, the maximum plan dimension shall be taken at the minimum section of the flare. For supports with a ratio less than 2.5, the provisions for piers of Article 5.11.4.2 shall apply.

A pier may be designed as a pier in its strong direction and a column in its weak direction.

5.11.4.1.1—Longitudinal Reinforcement

The area of longitudinal reinforcement shall not be less than 0.01 or more than 0.04 times the gross cross-section area, A_g .

C5.11.4.1

The definition of a column in this Article is provided as a guideline to differentiate between the additional design requirements for a wall-type pier and the requirements for a column. If a column or pier is above or below the recommended criterion, it may be considered to be a column or a pier, provided that the appropriate R-factor of Article 3.10.7.1 and the appropriate requirements of either Articles 5.11.4.1 or 5.11.4.2 are used. For columns with an aspect ratio less than 2.5, the forces resulting from plastic hinging will generally exceed the elastic design forces; consequently, the forces of Article 5.11.4.2 would not be applicable.

C5.11.4.1.1

This requirement is intended to apply to the full section of the columns. The lower limit on the column reinforcement reflects the traditional concern for the effect of time-dependent deformations as well as the desire to avoid a sizable difference between the flexural cracking and yield moments. Columns with less than 1 percent steel have also not exhibited good ductility (Halvorsen, 1987). The four-percent-maximum ratio is to avoid congestion and extensive shrinkage cracking and to permit anchorage of the longitudinal steel. The fifth edition (2010) of these Specifications limited this ratio to six percent, but this cap is lowered in the current edition because the boundaries for Zones 3 and 4 are significantly higher than in the previous edition, due to the increase in the return period for the design earthquake from 500 to 1,000 years. The four percent figure is consistent with that recommended in recent publications by NCHRP (2002 and 2006) and MCEER/ATC (2003).

5.11.4.1.2—Flexural Resistance

The biaxial strength of columns shall not be less than that required for flexure, as specified in Article 3.10.9.4. The column shall be investigated for both directional combinations of force effects specified in Article 3.10.8, at the extreme event limit state. The resistance factors of Article 5.5.4.2 shall be replaced for columns with either spiral, hoop, or tie reinforcement by the value of 0.9.

5.11.4.1.3—Column and Pile Bent Transverse Reinforcement for Shear

The factored shear force, V_u , on each principal axis of each column and pile bent shall be as specified in Article 3.10.9.4.

The amount of transverse reinforcement shall not be less than that specified in Article 5.7.3.

The following provisions apply to potential plastic hinge regions of column and pile bents:

- Potential plastic hinge regions shall be assumed to extend from the face of integral connections to superstructure, cap beam, or foundations a distance taken as the greater of:
 - the maximum cross-sectional dimension of the column or pile;
 - one-sixth of the clear height of the column or pile; or
 - 18.0 in.
- Potential plastic hinge regions at the bottom of pile bents shall be considered to extend from three pile diameters below to one pile diameter above the calculated point of maximum moment, but shall not extend less than 18.0 in. above the mud line.
- In potential plastic hinge regions, V_c shall be taken as that specified in Article 5.7.3, provided that the minimum factored axial compression force exceeds $0.10 f'_c A_g$. For compression forces less than $0.10 f'_c A_g$, V_c shall be taken to decrease linearly from the value given in Article 5.7.3 to zero at zero compression force.

C5.11.4.1.2

Columns are required to be designed biaxially and to be investigated for both the minimum and maximum axial forces. In the *AASHTO Guide Specifications for LRFD Seismic Bridge Design*, the recommended flexural resistance factor is 1.0. However, since these Specifications are force-based and do not explicitly calculate the ductility demand as in the *AASHTO Guide Specifications for LRFD Seismic Bridge Design*, limiting the factor to 0.9 is considered justified in lieu of a more rigorous analysis.

C5.11.4.1.3

Hoops offer the following advantages over spirals:

- Improved constructability when the transverse reinforcement must extend up into a bent cap or into a footing. Hoops can be used at potential plastic hinge regions of a compression member in combination with spirals in nonplastic hinge regions, or full height of the column in place of spirals.
- Ability to sample and perform destructive testing of in-situ splices prior to assembly.
- Breakage at a single location versus potential unwinding and greater loss of confinement leading to plastic hinge failure.

The requirements of this Article are intended to minimize the potential for a column shear failure. The design shear force is specified as that capable of being developed by either flexural yielding of the columns or the elastic design shear force. This requirement was added because of the potential for superstructure collapse if a column fails in shear.

A column may yield in either the longitudinal or transverse direction. The shear force corresponding to the maximum shear developed in either direction for noncircular columns should be used for the determination of the transverse reinforcement.

The concrete contribution to shear resistance is undependable within the plastic hinge zone, particularly at low axial load levels, because of full-section cracking under load reversals. As a result, the concrete shear contribution should be reduced for axial load levels less than $0.10 f'_c A_g$.

For a noncircular pile, this provision may be applied by substituting the larger cross-sectional dimension for the diameter.

5.11.4.1.4—Transverse Reinforcement for Confinement in Potential Plastic Hinge Regions

The cores of columns and pile bents shall be confined by transverse reinforcement in the expected plastic hinge regions. The transverse reinforcement for confinement shall have a yield strength not more than that of the longitudinal reinforcement, and the spacing shall be taken as specified in Article 5.11.4.1.5.

For a circular column, the volumetric ratio of spiral or hoop reinforcement, ρ_s , shall be determined as:

$$\rho_s = \frac{4A_{sp}}{(d_c s)} \geq 0.12 \frac{f'_c}{f_{yh}} \quad (5.11.4.1.4-1)$$

and shall satisfy the requirements of Article 5.6.4.6.

where:

- A_{sp} = cross-sectional area of spiral or hoop (in.²)
- d_c = core diameter of column measured to the outside of transverse reinforcement (in.)
- s = pitch or vertical spacing of transverse reinforcement (in.)
- f'_c = compressive strength of concrete for use in design (ksi)
- f_{yh} = specified minimum yield strength of transverse reinforcement (ksi) ≤ 100 ksi for elements and connections specified in Article 5.4.3.3; ≤ 75.0 ksi otherwise

Within potential plastic hinge regions, splices in spiral reinforcement shall be made by full-welded splices or by full-mechanical connections.

For a rectangular column, the total cross-sectional area, A_{sh} , of tie and cross-tie reinforcement shall satisfy both of the following:

$$A_{sh} \geq 0.30 s h_c \frac{f'_c}{f_{yh}} \left[\frac{A_g}{A_c} - 1 \right] \quad (5.11.4.1.4-2)$$

$$A_{sh} \geq 0.12 s h_c \frac{f'_c}{f_{yh}} \quad (5.11.4.1.4-3)$$

where:

- A_{sh} = total cross-sectional area of tie reinforcement, including supplementary cross-ties having a vertical spacing of s and crossing a section having a core dimension of h_c (in.²)
- s = pitch or vertical spacing of transverse reinforcement, not exceeding 4.0 in. (in.)

C5.11.4.1.4

Potential plastic hinge regions are generally located at the top and bottom of columns and pile bents. Detailing of seismic hooks has not been verified for reinforcement with yield strengths exceeding 75.0 ksi.

The main function of the transverse reinforcement specified in this Article is to ensure that the axial load carried by the column after spalling of the concrete cover will at least equal the load carried before spalling and to ensure that buckling of the longitudinal reinforcement is prevented. Thus, the spacing of the confining reinforcement is also important.

Careful detailing of the confining steel in the potential plastic hinge regions is required because of spalling and loss of concrete cover. With deformation associated with plastic hinging, the strains in the transverse reinforcement increase. Ultimate-level splices are required. Similarly, ties should be anchored by bending ends back into the core.

Figures C5.11.4.1.4-1 and C5.11.4.1.4-3 illustrate the use of Eqs. 5.11.4.1.4-2 and 5.11.4.1.4-3. The required total area of tie and cross-tie reinforcement should be determined for both principal axes of a rectangular or oblong column. Figure C5.11.4.1.4-3 shows the distance to be utilized for h_c and the direction of the corresponding reinforcement for both principal directions of a rectangular column.

Where ties and cross-ties are used for transverse column reinforcement, the maximum clear spacing of unrestrained longitudinal reinforcement is recommended to be 6.0 in. to reduce buckling after cover spalling. A maximum tie spacing of 14.0 in. is recommended for the laterally supported longitudinal bars to provide confinement.

Where a spiral or hoop cage is used, a maximum spacing of longitudinal bars of 8.0 in. center-to-center is recommended to help confine the column core.

While these Specifications allow the use of spirals, hoops, or ties and cross-ties for transverse column

- h_c = core dimension of tied column in the direction under consideration, measured to the outside of the tie (in.)
 A_g = gross area of section (in.²)
 A_c = area of column core measured to the outside of transverse reinforcement (in.²)
 f_{yh} = specified minimum yield strength of transverse reinforcement (ksi) ≤ 75.0 ksi

A_{sh} shall be determined for both principal axes of a rectangular column.

Seismic hooks, which consist of a 135-degree bend, plus an extension of not less than the larger of $6.0d_b$ or 3.0 in., shall be used for tie or hoop reinforcement in regions of potential plastic hinges. Such hooks and their required locations shall be detailed in the contract documents.

Tie reinforcement may be provided by single or overlapping ties and used with supplementary cross-ties.

Cross-ties inside potential plastic hinge regions shall meet the following requirements:

- The cross-tie bar size shall be the same as that used for the ties.
- The cross-tie shall consist of a seismic hook at one end and a hook of not less than 90 degrees with an extension of not less than $6.0d_b$ at the other end.
- The 90-degree hooks of adjacent cross-ties shall be alternated so that hooks of the same bend angle are not adjacent to each other both vertically and horizontally.
- A cross-tie may be a discontinuous bar with a Class A splice as specified in Article 5.10.8.4.3a on one end and a 180 degree hook with an extension of $6.0d_b$ on the other end.
- The cross-tie hooks shall engage peripheral longitudinal bars.

reinforcement, the use of spirals may be the most economical solution. Where more than one spiral or hoop cage is used to confine an oblong column core, the cages should be interlocked with longitudinal bars as shown in Figure C5.11.4.1.4-2.

Examples of transverse column reinforcement are shown herein.

Figure C5.11.4.1.4-1—Column Tie Details

Figure C5.11.4.1.4-2—Column Interlocking Spiral or Hoop Details

Figure C5.11.4.1.4-3—Column Tie Details

5.11.4.1.5—Spacing of Transverse Reinforcement for Confinement in Potential Plastic Hinge Regions

Transverse reinforcement for confinement shall be spaced not to exceed the lesser of the following:

- one-quarter of the minimum member dimension
- 4.0 in. center-to-center

5.11.4.1.6—Splices

The provisions of Article 5.10.8.4 shall apply for the design of splices.

Lap splices in longitudinal reinforcement shall not be used inside or outside of potential plastic hinge regions. Splices in longitudinal reinforcement using full-welded or full-mechanical couplers shall not be used within potential plastic hinge regions..

Full-welded or full-mechanical connection splices conforming to Article 5.10.8.4 may be used, provided that not more than alternate bars in each layer of longitudinal reinforcement are spliced at a section, and the distance between splices of adjacent bars is greater than 24.0 in. measured along the longitudinal axis of the column.

C5.11.4.1.6

In the past, it was often desirable to lap longitudinal reinforcement with dowels at the column base. This is undesirable for seismic performance because:

- The splice occurs in a potential plastic hinge region where requirements for bond is critical, and
- Lapping the main reinforcement will tend to concentrate plastic deformation close to the base and reduce the effective plastic hinge length as a result of stiffening of the column over the lapping region. This may result in a severe local curvature demand.

The prohibition on the use of lap splices in Seismic Zones 3 and 4 is extended to Seismic Zone 2 by virtue of Article 5.11.3.1.

Splices in seismic-critical elements should be designed for ultimate behavior under seismic deformation demands. Recommendations for acceptable strains are provided in Table C5.11.4.1.6-1. The strain demand at a cross-section is obtained from the deformation demand at that cross-section and the corresponding moment-curvature relationship. Traditional service level splices are only appropriate in components such as bent caps, girders, and footings, when not subjected to or protected from seismic damage by careful location and detailing of plastic hinge regions.

Table C5.11.4.1.6-1—Recommended Strain Limits in A706/A706M Bars, and Bars with Splices for Seismic Zones 3 and 4

	Minimum Required Resisting Strain, ϵ Bar only	Minimum Required Resisting Strain, ϵ Bar with Splice	Maximum Allowable Load Strain, ϵ	Resulting Factor of Safety
Ultimate	6% for #11 and larger 9% for #10 and smaller	6% for #11 and larger 9% for #10 and smaller	<2%	3 to 4.5
Service	(same as above)	>2%	<0.2%	>10
Lap (or welded / mechanical lap in lieu of lap splice)	(same as above)	>0.2%	<0.15% (unfactored loads) <0.2% (factored loads)	1.33

Limits are based on tests done by the California Department of Transportation and University of

5.11.4.2—Requirements for Wall-Type Piers

The provisions herein specified shall apply to the design for the strong direction of a pier. The weak direction of a pier may be designed as a column conforming to the provisions of Article 5.11.4.1, with the response modification factor for columns used to determine the design forces. If the pier is not designed as a column in its weak direction, the limitations for factored shear resistance herein specified shall apply.

The minimum reinforcement ratio, both horizontally, ρ_h , and vertically, ρ_v , in any pier shall not be less than 0.0025. The vertical reinforcement ratio shall not be less than the horizontal reinforcement ratio.

Reinforcement spacing, either horizontally or vertically, shall not exceed 18.0 in. The reinforcement required for shear shall be continuous and shall be distributed uniformly.

The factored shear resistance, V_r , in the pier shall be taken as the lesser of the following:

$$V_r = 0.253\lambda\sqrt{f'_c}bd, \quad (5.11.4.2-1)$$

$$V_r = \phi V_n \quad (5.11.4.2-2)$$

in which:

$$V_n = \left[0.063\lambda\sqrt{f'_c} + \rho_h f_y \right] bd \quad (5.11.4.2-3)$$

where:

- λ = concrete density modification factor, specified in Article 5.4.2.8
 f'_c = compressive strength of concrete for use in design (ksi)
 b = width of pier (in.)
 d = depth of pier (in.)
 f_y = specified minimum yield strength of reinforcement (ksi)
 ρ_h = ratio of area of horizontal shear reinforcement to area of gross concrete area of a vertical section

California-Berkeley. The demonstrated strain at ultimate resistance of butt-welded details was divided by the typical demand strain in order to document the factor of safety. Although current experimental limitations of other splice details performing at the service level preclude strain measurements, known values are shown in Table C5.11.4.1.6-1 for comparison. The variability of strain along the potential plastic hinge justifies the much higher factor of safety. Use of traditional splice details to resist extreme loading conditions where nonlinear behavior is desired and analyzed as such, are shown to be inefficient. ASTM A615/A615M steel is generally not permitted by Caltrans because of weldability and ductility concerns, and was not investigated.

C5.11.4.2

The requirements of this article are based on limited data available on the behavior of piers in the inelastic range. Consequently, the R-factor of 2.0 for piers is based on the assumption of minimal inelastic behavior.

The requirement that $\rho_v \geq \rho_h$ is intended to avoid the possibility of inadequate web reinforcements in piers, which are short in comparison to their height. Splices should be staggered in an effort to avoid weak sections.

Horizontal and vertical layers of reinforcement should be provided on each face of a pier. Splices in horizontal pier reinforcement shall be staggered, and splices in the two layers shall not occur at the same location.

5.11.4.3—Column Connections

The design force for the connection between the column and the cap beam superstructure, pile cap, or spread footing shall be as specified in Article 3.10.9.4.3. The development length for all longitudinal steel shall be 1.25 times that required for the full yield strength of reinforcement as specified in Article 5.10.8.

Column transverse reinforcement, as specified in Article 5.11.4.1.4, shall be continued for a distance equal to one-half the maximum column dimension but not less than 15.0 in. from the face of the column connection into the adjoining member.

The nominal shear resistance, V_n , provided by the concrete in the joint of a frame or bent in the direction under consideration, shall satisfy:

$$V_n \leq 0.380 b d \lambda \sqrt{f'_c} \quad (5.11.4.3-1)$$

where:

- b = width of column (in.)
- d = depth of column (in.)
- λ = concrete density modification factor, specified in Article 5.4.2.8
- f'_c = compressive strength of concrete for use in design (ksi)

5.11.4.4—Construction Joints in Piers and Columns

Where shear is resisted at a construction joint solely by dowel action and friction on a roughened concrete surface, the nominal shear resistance across the joint, V_n , shall be taken as:

$$V_n = (A_{vf} f_y + 0.75 P_u) \quad (5.11.4.4-1)$$

where:

- A_{vf} = the total area of reinforcement, including flexural reinforcement (in.²)
- P_u = minimum factored axial load as specified in Article 3.10.9.4 for columns and piers (kip)

5.11.4.5—Concrete Piles

5.11.4.5.1—General

In addition to the requirements specified for Zone 2, piles in Zones 3 and 4 shall conform to the provisions specified herein.

The requirement for a minimum of two layers of reinforcement in walls carrying substantial design shears is based on the premise that two layers of reinforcement will tend to “basket” the concrete and retain the integrity of the wall after cracking of the concrete.

C5.11.4.3

A column connection, as referred to in this article, is the vertical extension of the column area into the adjoining member.

The integrity of the column connection is important if the columns are to develop their flexural capacity. The longitudinal reinforcement should be capable of developing its overstrength capacity of $1.25f_y$. The transverse confining reinforcement of the column should be continued a distance into the joint to avoid a plane of weakness at the interface.

The strength of the column connections in a column cap is relatively insensitive to the amount of transverse reinforcement, provided that there is a minimum amount and that shear resistance is limited to the values specified.

C5.11.4.4

Eq. 5.11.4.4-1 is based on Eq. 22.9.4.2 of ACI 318-14 but is restated to reflect dowel action and frictional resistance.

5.11.4.5.2—Confinement Length

The upper end of every pile shall be reinforced and confined as a potential plastic hinge region, except where it can be established that there is no possibility of any significant lateral deflection in the pile. The potential plastic hinge region shall extend from the underside of the pile cap over a length of 2.0 pile diameters but not less than 24.0 in. If an analysis of the bridge and pile system interacting with the surrounding soil indicates that a plastic hinge can form at a lower level, the confinement length with the specified transverse reinforcement and closer pitch, as specified in Article 5.11.3.2, shall extend thereto.

5.11.4.5.3—Volumetric Ratio for Confinement

The volumetric ratio of transverse reinforcement within the confinement length shall be that for columns, as specified in Article 5.11.4.1.4.

5.11.4.5.4—Cast-in-Place Piles

For cast-in-place piles, longitudinal steel shall be provided for the full length of the pile. In the upper two thirds of the pile, the longitudinal steel ratio, provided by not less than four bars, shall not be less than 0.75 percent. For piles less than 24.0 in. in diameter, spiral reinforcement or equivalent hoops or ties of not less than #3 bars shall be provided at a pitch or spacing not exceeding 9.0 in., except that the pitch or spacing shall not exceed 4.0 in. within a length below the pile cap reinforcement of not less than 4.0 ft and where the volumetric ratio and splice details shall conform to Articles 5.11.4.1.4, 5.11.4.1.5, and 5.11.4.1.6.

5.11.4.5.5—Precast Piles

For precast piles, spiral ties shall not be less than #3 bars at a pitch not exceeding 9.0 in., except for the top 4.0 ft, where the pitch shall be 3.0 in. and the volumetric ratio and splice details shall conform to Article 5.11.4.1.4.

5.12—PROVISIONS FOR STRUCTURE COMPONENTS AND TYPES

5.12.1—Deck Slabs

Requirements for deck slabs in addition to those specified in Section 5 shall be as specified in Section 9.

C5.11.4.5.2

Note the special requirements for pile bents given in Article 5.11.4.1.

C5.11.4.5.4

See Article C5.11.3.2.2.

5.12.2—Slab Superstructures

5.12.2.1—Cast-in-Place Solid Slab Superstructures

Cast-in-place, longitudinally reinforced slabs may be either conventionally reinforced or prestressed and may be used as slab-type bridges.

The distribution of live load may be determined by a refined analysis or as specified in Article 4.6.2.3. Slabs and slab bridges designed for moment in conformance with Article 4.6.2.3 may be considered satisfactory for shear.

Edgebeams shall be provided as specified in Article 9.7.1.4.

Transverse distribution reinforcement shall be placed in the bottoms of all slabs, except culvert tops or bridge slabs, where the depth of fill over the slab exceeds 2.0 ft. The amount of the bottom transverse reinforcement may be determined by two-dimensional analysis, or the amount of distribution reinforcement may be taken as the percentage of the main reinforcement required for positive moment taken as:

- For longitudinal reinforced concrete construction:

$$\frac{100}{\sqrt{L}} \leq 50\% \quad (5.12.2.1-1)$$

- For longitudinal prestressed construction:

$$\frac{100}{\sqrt{L}} \frac{f_{pe}}{60} \leq 50\% \quad (5.12.2.1-2)$$

where:

L = span length (ft)

f_{pe} = effective stress in the prestressing steel (ksi)

Transverse shrinkage and temperature reinforcement in the tops of slabs shall conform to the requirements of Article 5.10.6.

5.12.2.2—Cast-in-Place Voided Slab Superstructures

5.12.2.2.1—Cross-Section Dimensions

Cast-in-place voided slab superstructures may be post-tensioned both longitudinally and transversely.

For circular voids, the center-to-center spacing of the voids should not be less than the total depth of the slab, and the minimum thickness of concrete taken at the centerline of the void perpendicular to the outside surface shall not be less than 5.5 in.

For rectangular voids, the transverse width of the void should not exceed 1.5 times the depth of the void,

C5.12.2.1

In this simple bridge superstructure, the deck slab also serves as the principal load-carrying component. The concrete slab, which may be solid, voided, or ribbed, is supported directly on the substructures.

The provisions are based on the performance of the relatively small span structures constructed to date. Any significant deviation from successful past practice for larger units that may become both structurally and economically feasible under these Specifications should be reviewed carefully.

the thickness of the web between voids should not be less than 20 percent of the total depth of the deck, and the minimum thickness of concrete above the voids shall not be less than 7.0 in.

The bottom flange depth shall satisfy the requirements specified in Article 5.12.3.5.1b.

Where the voids conform to the dimensional requirements herein and where the void ratio, based on cross-sectional area, does not exceed 40 percent, the superstructure may be analyzed as a slab, using either the provisions of Article 4.6.2.3 or a two-dimensional analysis for isotropic plates.

If the void ratio exceeds 40 percent, the superstructure shall be treated as cellular construction and analyzed as:

- A monolithic multicell box, as specified in Article 4.6.2.2.1, Type *d*;
- an orthotropic plate; or
- a three-dimensional continuum.

5.12.2.2.2—Minimum Number of Bearings

Columns may be framed into the superstructure, or a single bearing may be used for the internal supports of continuous structures. A minimum of two bearings shall be employed at end supports.

The transverse rotation of the superstructure shall not exceed 0.5 percent at service limit states.

5.12.2.2.3—Solid End Sections

A solid section at least 3.0 ft long but not less than five percent of the length of the span shall be provided at either end of a span. Post-tensioned anchorage zones shall satisfy the requirements specified in Article 5.9.5.6. In the absence of more refined analysis, the solid sections of the deck may be analyzed as a transverse beam distributing forces to bridge bearings and to post-tensioning anchorages.

5.12.2.2.4—General Design Requirements

For voided slabs conforming to the provisions of Article 5.12.2.2.1, global and local force effects due to wheel loads need not be combined. The top flange of deck with rectangular voids may be analyzed and designed as a framed slab or designed with the provisions of the empirical process, as specified in Article 9.7.2.

The top part of the slab over circular voids made with steel void-formers shall be post-tensioned transversely. At the minimum thickness of concrete, the average precompression after all losses, as specified in Article 5.9.3, shall not be less than 0.5 ksi. When transversely post-tensioned, no additional reinforcing steel need be provided above the circular voids.

C5.12.2.2.2

The high torsional stiffness of voided concrete decks and the inherent stability of horizontally curved continuous structures permits the use of a single support at internal piers. A minimum of two bearings are required at the abutments to ensure torsional stability in the end zones. If the torsional rotation requirement is not satisfied, pairs of bearings may be used at some internal piers.

C5.12.2.2.3

The intent is to provide for the distribution of concentrated post-tensioning and bearing forces to the voided sections. For relatively wide decks, the analysis of the solid sections as beams is an acceptable approximation. For deep and narrow decks, a three-dimensional analysis or use of the STM is advisable.

C5.12.2.2.4

Continuous voided decks should be longitudinally post-tensioned. Unless specified otherwise in this article, or required for construction purposes, additional global longitudinal reinforcement may be deemed to be unnecessary if longitudinal post-tensioning is used. The preference for longitudinal post-tensioning of continuous decks reflects the limited experience with this system in North America.

Experience indicates that due to a combination of transverse bending moment, shrinkage of concrete around the steel void-former and Poisson's effect, where steel void-formers are used, high transverse tensile stresses tend to develop at the top of the deck, resulting in excessive cracking at the centerline of the void. The

Transverse shrinkage and temperature steel at the bottom of the voided slab shall satisfy the requirements specified in Article 5.10.6.

5.12.2.2.5—Compressive Zones in Negative Moment Area

At internal piers, the part of the cross-section under compressive stresses may be considered as a horizontal column and reinforced accordingly.

5.12.2.2.6—Drainage of Voids

Adequate drainage of the voids shall be provided in accordance with the provisions of Article 2.6.6.5.

5.12.2.3—Precast Deck Bridges

5.12.2.3.1—General

Precast concrete units placed adjacent to each other in the longitudinal direction may be joined together transversely to form a deck system. Precast concrete units may be continuous either for transient loads only or for both permanent and transient loads. Span-to-span continuity, where provided, shall be in accordance with the provisions of Article 5.12.3.4.2.

Where structural concrete overlay is not provided, the minimum thickness of concrete shall be 3.5 in. at the top of round voided components and 5.5 in. for all other components.

minimum transverse prestress specified to counteract this tension is a conservative value. The intent of transverse temperature steel at the bottom of voided deck is also for control of cracks resulting from transverse positive moments due to post-tensioning.

The hidden solid transverse beam over an internal pier may be post-tensioned.

C5.12.2.2.5

Tests on two-span, continuous, post-tensioned structures indicate that first failure occurs in the bottom compressive zones adjacent to the bearing at the internal pier. The failure is thought to be caused by a combination of shear and compression at those points in the bottom flange. The phenomenon is not yet clearly understood, and no specific design provisions have been developed. At this time, the best that can be done is to treat the bottom chord as a column with a reinforcement ratio of one percent and column transverse reinforcement, as specified in Article 5.10.4.

C5.12.2.2.6

Occasional cracks large enough to permit entry of water into the voids may develop in these deck systems. The accumulating water adds to gravitational loads and may cause structural damage when it freezes.

C5.12.2.3.1

Precast units may have solid, voided, box, T- and double-T cross-sections.

Differential creep and shrinkage due to differences in age, concrete mix, environmental, and support conditions have been observed to cause internal force effects that are difficult to predict at the design phase. These force effects are often relieved by separation of the joints, causing maintenance problems and negatively affecting structural performance.

Standard AASHTO-PCI prestressed concrete voided slab and box-beam sections, which are commonly used to construct precast deck bridges, have been used successfully for many years in bridges with and without a structural concrete overlay. The standard prestressed concrete overlay slab sections have 3.5 in., 4.0 in. and 4.5 in. of concrete over 8.0 in., 10.0 in. and 12.0 in. diameter voids respectively. All standard box beams including both 3.0 and 4.0 ft wide sections, are detailed with 5.5 in. of concrete over rectangular voids with corner fillets.

5.12.2.3.2—Shear Transfer Joints

Precast longitudinal components may be joined together transversely by a shear key not less than 7.0 in. in depth. For the purpose of analysis, the longitudinal shear transfer joints shall be modeled as hinges.

The joint shall be filled with nonshrinking grout with a minimum compressive strength of 5.0 ksi at 24 hours.

*5.12.2.3.3—Shear-Flexure Transfer Joints**5.12.2.3.3a—General*

Precast longitudinal components may be joined together by transverse post-tensioning, cast-in-place closure joints, a structural overlay, or a combination thereof.

5.12.2.3.3b—Design

Decks with shear-flexure transfer joints should be modeled as continuous plates, except that the empirical design procedure of Article 9.7.2 shall not be used. The joints shall be designed as flexural components, satisfying the provisions of Article 5.12.2.3.3d.

5.12.2.3.3c—Post-Tensioning

Transverse post-tensioning shall be uniformly distributed in the longitudinal direction. Block-outs may be used to facilitate splicing of the post-tensioning ducts. The compressed depth of the joint shall not be less than 7.0 in., and the prestress after all losses shall not be less than 0.25 ksi therein.

5.12.2.3.3d—Longitudinal Construction Joints

Longitudinal construction joints between precast concrete flexural components shall consist of a key filled with a nonshrinkage mortar attaining a compressive strength of 5.0 ksi within 24 hours. The depth of the key should not be less than 5.0 in.

If the components are post-tensioned together transversely, the top flanges may be assumed to act as a monolithic slab. However, the empirical slab design specified in Article 9.7.2 is not applicable.

The amount of transverse prestress may be determined by either the strip method or two-dimensional analysis. The transverse prestress, after all losses, shall not be less than 0.25 ksi through the key. In the last 3.0 ft at a free end, the required transverse prestress shall be doubled.

C5.12.2.3.2

Many bridges have indications of joint distress where load transfer among the components relies entirely on shear keys because the grout is subject to extensive cracking. Long-term performance of the key joint should be investigated for cracking and separation.

C5.12.2.3.3a

These joints are intended to provide full continuity and monolithic behavior of the deck.

C5.12.2.3.3b

From the modeling point of view, these precast concrete deck systems are not different from cast-in-place ones of the same geometry.

C5.12.2.3.3c

When tensioning narrow decks, losses due to anchorage setting should be kept to a minimum. Ducts should preferably be straight and grouted.

The post-tensioning force is known to spread at an angle of 45 degrees or larger and to attain a uniform distribution within a short distance from the anchorage. The economy of prestressing is also known to increase with the spacing of ducts. For these reasons, the spacing of the ducts need not be smaller than about 4.0 ft or the width of the component housing the anchorages, whichever is larger.

C5.12.2.3.3d

This Article relates to deck systems composed entirely of precast beams of box, T-, and double-T sections, laid side-by-side and, preferably, joined together by transverse post-tensioning. The transverse post-tensioning tendons should be located at the centerline of the key.

Grinding of grout and concrete in the vicinity of the joint may be expected and specified for construction.

5.12.2.3.3e—Cast-in-Place Closure Joints

Concrete in the closure joint should have strength comparable to that of the precast components. The width of the longitudinal joint shall be large enough to accommodate development of reinforcement in the joint, but in no case shall the width of the joint be less than 12.0 in.

5.12.2.3.3f—Structural Overlay

Where a structural overlay is used to qualify for improved load distribution as provided in Articles 4.6.2.2.2 and 4.6.2.2.3, the thickness of structural concrete overlay shall not be less than 4.5 in. An isotropic layer of reinforcement shall be provided in accordance with the requirements of Article 5.10.6. The top surface of the precast components shall be roughened.

C5.12.2.3.3f

The composite overlay should be regarded as a structural component and should be designed and detailed accordingly.

5.12.3—Beams and Girders

5.12.3.1—General

The provisions specified herein shall be applied to the design of cast-in-place and precast beams as well as girders with rectangular, I, T, bulb-T, double-T, and open- and closed-box sections.

Precast beams may resist transient loads with or without a superimposed deck. Where a structurally separate concrete deck is applied, it shall be made composite with the precast beams in accordance with the provisions of Article 5.7.4.

The flange width considered to be effective in flexure shall be that specified in Article 4.6.2.6 or Article 5.7.3.4.

C5.12.3.1

This Article applies to linear elements, either partial or full span and either longitudinal or transverse. Segmental construction is covered in Article 5.12.5. There is a large variety of possible concrete superstructure systems, some of which may fall into either category. Precast deck bridges, which utilize girder sections with integral decks, are covered in Article 5.12.2.3.

Components that directly carry live loads, i.e., incorporated elements of the deck, should be designed for the applicable provisions of Section 9 and with particular reference to minimum dimension requirements and the way the components are to be joined to provide a continuous deck.

5.12.3.2—Precast Beams

5.12.3.2.1—Preservice Conditions

The preservice conditions of prestressed girders for shipping and erection shall be the responsibility of the contractor.

C5.12.3.2.1

The *AASHTO LRFD Bridge Construction Specifications* place the responsibility on the Contractor to provide adequate devices and methods for the safe storage, handling, erection, and temporary bracing of precast members. However, these preservice conditions may govern and should be considered in the design, as discussed in Article 2.5.3.

5.12.3.2.2—Extreme Dimensions

The thickness of any part of precast concrete beams shall not be less than:

C5.12.3.2.2

The 2.0-in. minimum dimension relates to bulb-T and double-T types of girders on which cast-in-place

Top flange.....	2.0 in.
Web, nonpost-tensioned.....	5.0 in.
Web, post-tensioned	6.5 in.
Bottom flange	5.0 in.

The maximum dimensions and weight of precast members manufactured at an offsite casting yard shall conform to local hauling restrictions.

5.12.3.2.3—Lifting Devices

If it is anticipated that anchorages for lifting devices will be cast into the face of a member that will be exposed to view or to corrosive materials in the completed structure, any restriction on locations of embedded lifting devices, the depth of removal, and the method of filling the cavities after removal shall be shown in the contract documents. The depth of removal shall be not less than the depth of cover required for the reinforcement.

5.12.3.2.4—Detail Design

All details of reinforcement, connections, bearing seats, inserts, or anchors for diaphragms, concrete cover, openings, and fabrication and erection tolerances shall be shown in the contract documents. For any details left to the Contractor's choice, such as prestressing materials or methods, the submittal and review of working drawings shall be required.

5.12.3.2.5—Concrete Strength

For slow curing concretes, the 90-day compressive strength may be used for all stress combinations that occur after 90 days, provided that the gain in strength is verified by prior tests for the concrete mix utilized.

The 90-day strength of slow curing concretes may be estimated as 115 percent of the 28-day concrete strength.

5.12.3.3—Bridges Composed of Simple Span Precast Girders Made Continuous

5.12.3.3.1—General

The provisions of this Article shall apply at the service and strength limit states, as applicable, for multi-

decks are used. The 5.0-in. and 6.5-in. web thicknesses have been successfully used by contractors experienced in working to close tolerances. The 5.0-in. limit for bottom flange thickness normally relates to box-type sections.

For highway transportation, the permissible load size and weight limits are constantly being revised. For large members, an investigation should be made prior to design to ensure transportability. Investigations may include driving the route or surveying route portions with known vertical or horizontal clearance problems. Contract documents should alert the contractor to weight and permitting complications as well as the possibility of law enforcement escort requirements.

When the weight or dimensions of a precast beam exceed local hauling restrictions, field splices conforming to the requirements of Article 5.12.3.4.2 may be used.

C5.12.3.2.3

The *AASHTO LRFD Bridge Construction Specifications* allow the Contractor to select the type of lifting device for precast members provided that the Contractor accepts responsibility for their performance. Anchorages for lifting devices generally consist of loops of prestressing strand or nonprestressed reinforcement, with their tails embedded in the concrete or threaded anchorage devices that are cast into the concrete.

C5.12.3.2.4

The *AASHTO LRFD Bridge Construction Specifications* include general requirements pertaining to the preparation and review of working drawings, but the contract documents should specifically indicate when they are required.

C5.12.3.2.5

This Article recognizes the behavior of slow-curing concretes, such as those containing fly-ash. It is not often that a bridge is opened to traffic before the precast components are 90 days old. The Designer may now take advantage of this, provided that the gain in strength has previously been verified by testing of the utilized concrete mix.

C5.12.3.3.1

The type of bridge covered by this Article is popular due to its simplicity of construction, especially

span bridges composed of simple-span precast girders with continuity diaphragms cast between the ends of the girders at continuous and integral supports and with positive moment reinforcement extending from the girder ends into the continuity diaphragms. Spans with concrete continuity diaphragms connecting girders with positive moment reinforcement may be considered continuous for loads placed on the bridge after the continuity diaphragm has attained adequate strength.

The requirements herein do not apply to multi-span bridges made continuous in the deck without continuity diaphragms. These are typically referred to as link-slab systems. The girders in link slab systems are designed as simple span, and supplemental reinforcement is provided in the deck at interior supports for crack control.

Multi-span bridges composed of precast girders with continuity diaphragms at interior supports that are designed as a series of simple spans are not required to satisfy these requirements unless the age of the precast concrete is less than 28 days at the time continuity is established.

These requirements supplement the requirements of other sections of these Specifications for prestressed concrete components that are not segmentally constructed.

in cold weather regions of the U.S. The girders are designed as simple span for their own self-weight and deck weight, and continuous for superimposed dead loads, live loads, and additional in-service loads. It is generally constructed with a composite deck slab connected to concrete continuity diaphragms at interior pier supports. The deck slab contains negative moment continuity reinforcement, while the girders have reinforcement projecting into the concrete continuity diaphragms for the primary purpose of controlling cracks at the girder-diaphragm interface. With proper design and detailing, precast members used without a composite deck may also be made continuous for loads applied after continuity is established. Details of this type of construction are discussed in Miller et al. (2004).

The Designer may choose to design a multi-span bridge as a series of simple spans that are not embedded into cast-in-place diaphragms but have a continuously reinforced deck slab over the pier supports. Such a system is called a link-slab system and has been widely used in many parts of the U.S. as it eliminates the use of high-maintenance expansion joint details over the piers. For such systems, no positive moment continuity reinforcement is required as the girders are allowed to rotate at the pier supports.

The Designer may also choose to design a multi-span bridge as a series of simple spans but detail it as continuous with continuity diaphragms where the girders are actually embedded a significant length into the diaphragms, resulting in a rigid girder-diaphragm connection. This approach has been used successfully in several parts of the country. For this system, continuity reinforcement should be provided to cover all loading combinations, including the volume change restraint moment covered in this Article. For high seismicity zones of the U.S. where this system is popular, seismic effects are likely to control the amount of positive moment reinforcement required at the pier supports.

Positive moment connections improve the structural integrity of a bridge, increasing its ability to resist extreme event and unanticipated loadings. These connections also control cracking that may occur in the continuity diaphragm. Therefore, it is recommended that positive moment connections be provided in all bridges detailed as continuous for live load.

5.12.3.3.2—Restraint Force Effects

The bridge shall be designed for restraint force effects that may develop from time-dependent deformations (SH, CR, PS) or transient load effects (TU, TG, SE) that occur in-part or entirely after continuity is established. Restraint force effects shall not be included in any load combination where the effect of the restraint force effect is to reduce the total force effect.

C5.12.3.3.2

Deformations that occur after continuity is established from time-dependent effects such as creep, shrinkage and temperature variation cause restraint forces.

Restraint force effects are computed at interior supports of continuous bridges but affect the design force effects at all locations on the bridge. Studies show that restraint moments can be positive or negative. The magnitude and direction of the moments depend on

girder age at the time continuity is established, properties of the girder and slab concrete, and bridge and girder geometry. (Mirmiran et al., 2001) (Miller et al., 2004) (Tuan et al., 2018). The data show that the later continuity is formed, the lower the predicted values of positive restraint moment which will form. Since positive restraint moments are generally not desirable except where the superstructure is intended to behave as though it were integral with the substructure, waiting as long as possible after the girders are cast to establish continuity and cast the deck appears to be beneficial. However, this is not always feasible due to the desire for accelerated bridge construction or the possibility of having to erect girders and establish continuity in a short period of time.

Most analysis indicates that differential shrinkage between the girder and deck mitigates positive restraint moment formation.

Estimated restraint moments are highly dependent on actual material properties and project schedules and the computed restraint moments may never develop. Therefore, a critical design moment must not be reduced by a restraint moment in case the restraint moment does not develop.

Restraint moment due to creep may be computed as $M_{rc} = \delta_1 (M_{girder} + M_{ps}) + \delta_2 M_{deck}$, where M_{girder} , M_{ps} , and M_{deck} are the girder self-weight, prestress, and deck self-weight moments, respectively, at the face of the girder computed as if the bridge was continuous at the time of load application,

$$\delta_1 = \frac{E_c (\psi_b(t_f, t_i) - \psi_b(t_d, t_i))}{E_{ci} (1 + 0.7 \psi_b(t_f, t_d))} \quad (C5.12.3.3.2-1)$$

$$\delta_2 = \frac{E_c (\psi_b(t_f, t_i) - \psi_b(t_d, t_i))}{E_{ci} (1 + \psi_b(t_f, t_d))} \quad (C5.12.3.3.2-2)$$

Continuity is assumed to occur at time of deck placement, t_d . The total restraint moment, M_{res} , is the sum of the restraint moment due to creep, M_{rc} , restraint moment due to deck shrinkage, M_{sh} , restraint moment due to temperature gradient, M_{tg} , and elastic moments due to superimposed dead loads, M_{sdl} ; $M_{res} = M_{rc} + M_{sh} + M_{tg} + M_{sdl}$. Axial restraint forces can develop for creep, T_{cr} , deck shrinkage, T_{sh} , uniform temperature change, T_{tu} , and temperature gradient, T_{tg} ; $T_{res} = T_{cr} + T_{sh} + T_{tu} + T_{tg}$. Restraint moments and forces due to creep, deck shrinkage, and temperature gradient may be calculated using the initial strain theory as given by Dilger (1982) and Tuan et al. (2018). This pseudo-elastic analysis method is performed according to the following steps:

- (1) Allow components of the member, for example the precast girder and deck components, to deform freely due to volume change effect.

- (2) Restrain each component with a fictitious restraining force effect to restore displacement compatibility between components.
- (3) Apply force effects that are equal and opposite to the fictitious restraining force effects to the composite member to restore equilibrium.

The sum of deformations and force effects in the three steps results in final equilibrium. The method is fully covered with a detailed numerical example in Tuan et al (2018) and has been adopted in a joint PCI/fib Bulletin (2020).

In long bridges with multiple spans, daily and seasonal temperature changes may have a significant influence that must be considered for analysis of restraint force effects.

5.12.3.3.3—Material Properties

Creep and shrinkage properties of the girder concrete and the shrinkage properties of the deck slab concrete shall be determined from either of the following:

- Tests of concrete using the same proportions and materials that will be used in the girders and deck slab. Measurements shall include the time-dependent rate of change of these properties.
- The provisions of Article 5.4.2.3.

The restraining effect of reinforcement on concrete shrinkage may be considered.

C5.12.3.3.3

The development of restraint moments is highly dependent on the creep and shrinkage properties of the girder and deck concrete. Since these properties can vary widely, measured properties should be used when available to obtain the most accurate analysis. However, these properties are rarely available during design. Therefore, the provisions of Article 5.4.2.3 may be used to estimate these properties.

Because longitudinal reinforcement in the deck slab restrains the shrinkage of the deck concrete, the apparent shrinkage is less than the free shrinkage of the deck concrete. This effect may be estimated using an effective concrete shrinkage strain, $\epsilon_{\text{effective}}$, which may be taken as:

$$\epsilon_{\text{effective}} = \epsilon_{sh} \left(\frac{A_c}{A_{tr}} \right) \quad (\text{C5.12.3.3.3-1})$$

where:

ϵ_{sh}	= unrestrained shrinkage strain for deck concrete (in./in.)
A_c	= gross area of concrete deck slab (in. ²)
A_{tr}	= area of concrete deck slab with transformed longitudinal deck reinforcement (in. ²)
	= $A_c + A_s(n - 1)$
A_s	= total area of longitudinal deck reinforcement (in. ²)
n	= modular ratio between deck concrete and reinforcement
	= $E_s / E_{c \text{ deck}}$
$E_{c \text{ deck}}$	= modulus of elasticity of deck concrete (ksi)

Eq. C5.12.3.3.3-1 is based on simple mechanics (Abdalla et al., 1993). If the amount of longitudinal reinforcement varies along the length of the slab, the

5.12.3.3.4—Age of Girder When Continuity Is Established

The minimum age of the precast girder when continuity is established should be specified in the contract documents. This age shall be used for calculating restraint force effects due to creep and shrinkage. If no age is specified, a reasonable, but conservative estimate of the time continuity is established shall be used for all calculations of restraint force effects.

5.12.3.3.5—Service Limit State

Simple-span precast girders made continuous shall be designed to satisfy service limit state stress limits given in Article 5.9.2.3. For service load combinations that involve traffic loading, tensile stresses in prestressed members shall be investigated using the Service III load combination specified in Table 3.4.1-1.

At the service limit state, when tensile stresses develop at the top of the girders near interior supports, the tensile stress limits specified in Table 5.9.2.3.1b-1 for other than segmentally constructed bridges shall apply. The design concrete compressive strength of the girder concrete, f'_{ci} , shall be substituted for f'_{ci} in the stress limit equations. The Service III load combination shall be used to compute tensile stresses for these locations. Alternatively, the top of the precast girders at interior supports may be designed as reinforced concrete members at the strength limit state. In this case, the stress limits for the service limit state shall not apply to this region of the precast girder.

If tensile stresses develop in the bottom flange at the ends of the precast girders and cracking due to volume change force effects is not allowed, the tensile stress limits specified in Table 5.9.2.3.2b-1 for the service limit state for other than segmentally constructed bridges shall apply. If the bottom fibers of the girder at the face of the diaphragm are allowed to have limited cracking due to volume change force effects, the provisions of this Article shall apply including limiting the reinforcement stress that is provided to control cracking to 36.0 ksi.

average area of longitudinal reinforcement may be used to calculate the transformed area.

C5.12.3.3.4

Analytical studies show that the age of the precast girder when continuity is established is an important factor in the development of restraint moments (Mirmiran et al., 2001). According to analysis, establishing continuity when girders are young causes larger positive moments to develop. Therefore, although no minimum girder age for continuity is specified, a reasonable early age of 28 days may be used. An age of seven days was reported to have been used. However, the use of seven days as the age of girders when continuity is established results in a large positive restraint moment that must be carefully estimated with the Owner's approval.

When girders are relatively young when continuity is established, some cracking due to positive moment may occur near the girder-diaphragm interface. Frosch (1999) shows that if the tensile stress in the bottom continuity reinforcement due to the restraint moment is limited to 36.0 ksi, it can tolerate this cracking without appreciable loss of continuity.

C5.12.3.3.5

Tensile stresses under service limit state loadings may occur at the top of the girder near interior supports. The tensile zone is close to the end of the girder, so adding or debonding pretensioned strands has little effect in reducing the tensile stresses. Therefore, the limits specified for temporary stresses have been used to address this condition, with modification to use the design concrete compressive strength. This provision provides some relief for the potentially high tensile stresses that may develop at the ends of girders because of negative service load moments.

The deck slab is not a prestressed element. Therefore, the tensile stress limits do not apply. It has been customary to apply the compressive stress limits to the deck slab.

The tension force resulting from positive continuity moments is transferred to the girders by the positive moment reinforcement (strands or nonprestressed reinforcement) (Okeil et al., 2013). At girder ends, prestressing is not fully effective within the transfer length, and the tension force is locally applied to the precast girder's bottom flange. These two factors may lead to tensile stresses that exceed the cracking stress for girder concrete (Hossain and Okeil, 2014). Therefore, the tensile stresses caused by the positive continuity moment due to creep, shrinkage, and temperature changes should be checked to avoid girder end cracking. The effective prestress force used in the check should consider the transfer length, and in the

A cast-in-place composite deck slab shall not be subject to the tensile stress limits for the service limit state specified in Table 5.9.2.3.2b-1. The requirements of Article 5.6.7 shall apply.

Restraining moment is caused by the following:

- Creep of girder concrete due to prestressing and permanent loads
- Deck shrinkage
- Elastic effects of superimposed dead loads, live loads, and temperature gradient.

Analysis for the aforementioned effects may be conducted using the initial strain theory or other creep modeling methods.

5.12.3.3.6—Strength Limit State

Negative moment connections between precast girders and a continuity diaphragms shall be designed for the strength limit state.

The reinforcement in the deck slab shall be proportioned to resist negative design moments at the strength limit state.

Positive moment connections between precast girders and continuity diaphragms do not need to be evaluated at the strength limit state.

5.12.3.3.7—Negative Moment Connections

The reinforcement in a cast-in-place, composite deck slab in a multi-span precast girder bridge made continuous shall be proportioned to resist negative design moments at the strength limit state.

Longitudinal reinforcement used for the negative moment connection over an interior pier shall be anchored in regions of the slab that are in compression at strength limit states and shall satisfy the requirements of Article 5.10.8.1.2c. The termination of this reinforcement shall be staggered. All longitudinal reinforcement in the deck slab may be used for the negative moment connection.

Negative moment connections between precast girders into or across the continuity diaphragm shall satisfy the requirements of Article 5.10.8.4. These connections shall be permitted where the bridge is designed with a composite deck slab and shall be required where the bridge is designed without a composite deck slab. Additional connection details shall

absence of a more comprehensive analysis, the effective concrete area that resists the tension force should not exceed the area of the bottom flange.

Approximate analysis may be conducted assuming gross cross-section properties, without accounting for reduced stiffness due to cracking of parts of the members under service load effects. The resulting restraining moment may be reduced by 10 percent to account for a reduction in stiffness due to cracking at the girder-diaphragm interface. Positive moment continuity reinforcement should be provided such that the stress in the reinforcement does not exceed 36.0 ksi.

The tension force in the bottom continuity reinforcement may be computed using the theory of elasticity assuming a cracked section or by dividing the reduced restraining moment by an assumed internal lever arm of $0.9h$, where h is the total depth of the composite girder, including the deck, and assuming half of the axial restraining forces due to deck shrinkage and thermal gradient are resisted by the bottom reinforcement; $T = \frac{0.9M_{res}}{0.9h} + \frac{T_{res}}{2}$. The required area of

reinforcement is computed by dividing the tensile force by the stress limit $f_s = 36.0 \text{ ksi}$; $A_s = \frac{T}{f_s}$.

C5.12.3.3.6

The continuity diaphragm is not prestressed concrete, so the stress limits for the service limit state do not apply. Positive moment connections to it are designed primarily for crack control using provisions for reinforced concrete elements.

C5.12.3.3.7

Research at PCA (Kaar et al., 1961) and years of experience show that the reinforcement in a composite deck slab can be proportioned to resist negative design moments in a continuous bridge.

Limited tests on continuous model and full size structural components indicate that, unless the reinforcement is anchored in a compressive zone, the effectiveness becomes questionable at the strength limit state (Priestley et al., 1993). The termination of the longitudinal deck slab reinforcement is staggered to minimize potential deck cracking by distributing local force effects.

A negative moment connection between precast girders and the continuity diaphragm is not typically provided, because the deck slab reinforcement is usually proportioned to resist the negative design moments. However, Ma et al. (1998) suggest that mechanical connections between the tops of girders may also be used for negative moment connections, especially when

be permitted if the strength and performance of these connections is verified by analysis or testing.

The requirements of Article 5.6.3 shall apply to the reinforcement in the deck slab and at negative moment connections at continuity diaphragms.

5.12.3.3.8—Positive Moment Connections

5.12.3.3.8a—General

The stress in positive moment continuity reinforcement, in both the girder and continuity diaphragm, shall not exceed 36.0 ksi.

Three types of connections are permitted:

- Pretensioning strands extended beyond the end of the girder and anchored into the continuity diaphragm. These strands shall be bonded continuously through the length of the girder.
- Nonprestressed reinforcement embedded in the precast girders and developed into the continuity diaphragm.
- Any connection detail shown by analysis, testing, or as approved by the bridge Owner to provide adequate positive moment resistance.

Additional requirements for connections made using each type of reinforcement are given in subsequent Articles.

The critical section for the development of positive moment reinforcement into the continuity diaphragm shall be taken at the face of the diaphragm. The critical section for the development of positive moment reinforcement into the precast girder shall consider conditions in the girder as specified in this article for the type of reinforcement used.

5.12.3.3.8b—Positive Moment Connection Using Prestressing Strand

Only straight pretensioning strands that are bonded continuously through the length of the girder may be extended into the continuity diaphragm as positive moment reinforcement. The extended strands shall be anchored into the diaphragm by bending the strands into a 90-degree hook, or by providing adequate length to ensure development to the stress limit in Article 5.12.3.3.8a, or by anchorage with a mechanical device attached to the extended strands.

continuity is established prior to placement of the deck slab. If a composite deck slab is not used on the bridge, a negative moment connection between girders is required to obtain continuity. Mechanical reinforcement splices have been successfully used to provide a negative moment connection between box beam bridges that do not have a composite deck slab.

C5.12.3.3.8a

Both embedded bar and extended strand connections have been used successfully to provide positive moment resistance. Test results (Miller et al., 2004) indicate that connections using the two types of reinforcement perform similarly under both static and fatigue loads and both have adequate strength to resist the applied moments if designed appropriately. However, the use of bars is not as cost effective as the use of the strands, which are already in the girder. Furthermore, bars have to be carefully detailed to avoid congestion at the beam end and to avoid stress concentration caused by their termination in the girder and concrete continuity diaphragm.

Editions of these Specifications prior to 2024 were based on analytical studies (Mirmiran et al., 2001) that suggested a minimum amount of reinforcement, corresponding to a capacity of $0.6M_{cr}$ is needed to develop adequate resistance to positive restraint moments. These same studies showed that a positive moment connection with a capacity greater than $1.2M_{cr}$ provides only minor improvement in continuity behavior over a connection with a capacity of $1.2M_{cr}$. However, the recommendations resulted in excessive reinforcement to satisfy the restraint moment demand.

C5.12.3.3.8b

Strands that are not bonded continuously through the length of the girder may not be used as reinforcement for the positive moment connection. There are no requirements for development of the strand into the girder because the strands run continuously through the precast girder.

Noppakunwii et al. (2002) developed girder diaphragm connection details using bent strand extending from ends of girder. Tsevtanova et al. (2017) developed girder-diaphragm connection details using plates and strand chucks attached to the ends of extended strands. These details have been in use by a number of states with satisfactory performance.

If the calculated number of strands is relatively small, it is recommended that a minimum of 8 strands be extended into the diaphragm to ensure adequate anchorage. Furthermore, it is good practice to embed the girder a minimum of 8.0 in. into the diaphragm in

order to allow for some prestress development in the girder at the face of the diaphragm.

5.12.3.3.8c—Positive Moment Connection Using Nonprestressed Reinforcement

C5.12.3.3.8c

The anchorage of nonprestressed reinforcement used for positive moment connections shall satisfy the requirements of Article 5.10.8 and the additional requirements of this article. Where positive moment reinforcement is added between pretensioned strands, the difficulty of concrete consolidation and its effect on the bond of reinforcement shall be considered.

The reinforcement shall be embedded beyond the inside edge of the bearing area a distance at least equal the development length of the strands.

Where multiple bars are used for a positive moment connection, the termination of the reinforcement shall be staggered in pairs symmetrical about the centerline of the precast girder.

Potential cracks are more likely to form in the precast girder at the inside edge of the bearing area and locations of termination of debonding. Since cracking within the development length reduces the effectiveness of the development, the reinforcement should be detailed to avoid this condition. It is recommended that reinforcement be extended beyond the development length of the strands in order to allow for adequate transition of forces in the positive moment zone. The termination of the positive moment reinforcement is staggered to reduce the potential for cracking at the ends of the bars.

5.12.3.3.8d—Details of Positive Moment Connection

C5.12.3.3.8d

Positive moment reinforcement shall be placed in a pattern that is symmetrical, or as nearly symmetrical as possible, about the centerline of the cross-section.

Fabrication and erection issues shall be considered in the detailing of positive moment reinforcement in the continuity diaphragm. Reinforcement from opposing girders shall be detailed to mesh during erection without significant conflicts. Reinforcement shall be detailed to enable placement of anchor bars and other reinforcement in the continuity diaphragm.

Miller et al. (2004) suggest that reinforcement patterns that have significant asymmetry may result in unequal bar stresses that can be detrimental to the performance of the positive moment connection.

With some girder shapes, it may not be possible to install prebent hooked bars without the hook tails interfering with the formwork. In such cases, a straight bar may be embedded and then bent after the girder is fabricated. Such bending is generally accomplished without heating and the bend must be smooth with a minimum bend diameter conforming to the requirements of Table 5.10.2.3-1. If the Engineer allows the reinforcement to be bent after the girder is fabricated, the contract documents shall indicate that field bending is permissible and shall provide requirements for such bending. Since requirements regarding field bending may vary, the preferences of the Owner should be considered.

Hairpin bars (a bar with a 180-degree bend with both legs developed into the precast girder) have been used for positive moment connections to eliminate the need for post-fabrication bending of the reinforcement and reduce congestion in the continuity diaphragm.

5.12.3.3.9—Continuity Diaphragms

C5.12.3.3.9

The design of continuity diaphragms at interior supports may be based on the strength of the concrete in the precast girders.

Precast girders may be embedded into continuity diaphragms.

If horizontal diaphragm reinforcement is passed through holes in the precast beam or is attached to the precast element using mechanical connectors, the end precast element shall be designed to resist positive moments caused by superimposed dead loads, live loads,

The use of the increased concrete strength is permitted because the continuity diaphragm concrete between girder ends is confined by the girders and by the continuity diaphragm extending beyond the girders. It is recommended that this provision be applied only to conditions where the portion of the continuity diaphragm that is in compression is confined between ends of precast girders.

The width of the continuity diaphragm must be large enough to provide the required embedment for the

creep and shrinkage of the girders, shrinkage of the deck slab, and temperature effects. Design of the end of the girder shall account for the reduced effect of prestress within the transfer length.

Where ends of girders are not directly opposite each other across a continuity diaphragm, the diaphragm must be designed to transfer forces between girders. Continuity diaphragms shall also be designed for situations where an angle change occurs between opposing girders.

development of the positive moment reinforcement into the diaphragm. An anchor bar with a diameter equal to or greater than the diameter of the positive moment reinforcement may be placed in the corner of a 90-degree hook or inside the loop of a 180-degree hook bar to improve the effectiveness of the anchorage of the reinforcement.

Several construction sequences have been successfully used for the construction of bridges with precast girders made continuous. When determining the construction sequence, the Engineer should consider the effect of girder rotations and restraint as the deck slab concrete is being placed.

Miller et al. (2004) show that embedding precast girders 6.0 in. into continuity diaphragms improves the performance of positive moment connections. The observed stresses in the positive moment reinforcement in the continuity diaphragm were reduced compared to connections without girder embedment.

The connection between precast girders and the continuity diaphragm may be enhanced by passing horizontal reinforcement through holes in the precast beam or attaching the reinforcement to the beam by embedded connectors. Miller et al. (2004) and Salmons (1980) show that such reinforcement stiffens the connection. The use of such mechanical connections requires that the end of the girder be embedded into the continuity diaphragm. Tests of continuity diaphragms without mechanical connections between the girder and diaphragm show the failure of connection occurs by the beam end pulling out of the diaphragm with all of the damage occurring in the diaphragm. Tests of connections with horizontal bars show that cracks may form in the end of the precast girder outside the continuity diaphragm if the connection is subjected to a significant positive moment. Such cracking in the end region of the girder may not be desirable.

A method such as given in Article 5.8.2 may be used to design a continuity diaphragm for these conditions.

5.12.3.4—Spliced Precast Girders

5.12.3.4.1—General

The provisions herein apply to precast girders fabricated in segments that are joined or spliced longitudinally to form the girders in the final structure.

The requirements specified herein shall supplement the requirements of other Sections of these Specifications for other than segmentally constructed bridges. There-fore, spliced precast girder bridges shall not be considered as segmental construction for the purposes of design. For special design cases, additional provisions for segmental construction found in Article 5.12.5 and other Articles in these Specifications may be used where appropriate.

The method of construction assumed for the design shall be shown in the contract documents. All supports required prior to the splicing of the girder shall be shown on the contract documents, including elevations and

C5.12.3.4.1

reactions. The stage of construction during which the temporary supports are removed shall also be shown on the contract documents.

The contract documents shall indicate alternative methods of construction permitted and the Contractor's responsibilities if such methods are chosen. Any changes by the Contractor to the construction method or to the design shall comply with the requirements of Article 5.12.5.5.

Stresses due to changes in the statical system, in particular, the effects of the application of load to one structural system and its removal from a different structural system, shall be accounted for. Redistribution of such stresses by creep shall be taken into account and allowance shall be made for possible variations in the creep rate and magnitude.

Spliced girder superstructures which satisfy all service limit state requirements of this article may be designed as fully continuous at all limit states for loads applied after the girder segments are joined.

Prestress losses in spliced precast girder bridges may be estimated using the provisions for other than segmentally constructed bridges in Article 5.9.3. The effects of combined pretensioning and post-tensioning and staged post-tensioning shall be considered.

Where required, the effects of creep and shrinkage in spliced precast girder bridges may be estimated using the provisions for other than segmentally constructed bridges in Article 5.4.2.3.

Precast deck girder bridges, for which some or all of the deck is cast integrally with a girder, may be spliced. Spliced structures of this type, which have longitudinal joints in the deck between each deck girder, shall comply with the additional requirements of Article 5.12.2.3.

Spliced precast girders may be made continuous for some permanent loads using details for simple span precast girders made continuous. In such cases, design shall conform to the applicable requirements of Article 5.12.3.3.

5.12.3.4.2—Joints Between Spliced Girders

5.12.3.4.2a—General

Joints between girder segments shall be either cast-in-place closure joints or match-cast joints. Match-cast joints shall satisfy the requirements of Article 5.12.5.4.2.

The sequence of placing concrete for the closure joints and deck shall be specified in the contract documents.

Spliced precast girder bridges may be distinguished from what is referred to as “segmental construction” elsewhere in these Specifications by several features which typically include:

- The lengths of some or all segments in a bridge are a significant fraction of the span length rather than having a number of segments in each span. In some cases, the segment may be the full span length.
- Design of joints between girder segments at the service limit state does not typically govern the design for the entire length of the bridge for either construction or for the completed structure.
- Cast-in-place closure joints are usually used to join girder segments rather than match-cast joints.
- The bridge cross-section is comprised of several individual girders with a cast-in-place concrete composite deck rather than precasting the full width and depth of the superstructure as one piece. In some cases, the deck may be divided into pieces that are integrally cast with each girder. A bridge of this type is completed by connecting the girders across the longitudinal joints.
- Girder sections are used, such as bulb tee or open-topped trapezoidal boxes, rather than closed cell boxes with wide monolithic flanges.

Provisional ducts are required for segmental construction (Article 5.12.5.3.9a) to provide for possible adjustment of prestress force during construction. Similar requirements are not given for spliced precast girder bridges because of the redundancy provided by a greater number of webs and tendons, and typically lower friction losses because of fewer joint locations.

The method of construction and any required temporary support is of paramount importance in the design of spliced precast girder bridges. Such considerations often govern final conditions in the selection of section dimensions and reinforcing and/or prestressing.

C5.12.3.4.2a

This Article codifies current best practice, which allows the Designer considerable latitude to formulate new structural systems. The great majority of in-span construction joints have been post-tensioned. Conventionally reinforced joints have been used in a limited number of bridges.

Cast-in-place closure joints are typically used in spliced girder construction. Machined bulkheads have been used successfully to emulate match-cast epoxy joints for spliced girders. Prestress, dead load, and creep effects may cause rotation of the faces of the match-cast

epoxy joints prior to splicing. Procedures for splicing the girder segments that overcome this rotation to close the match-cast joint should be shown on the contract plans.

5.12.3.4.2b—Details of Closure Joints

Precast concrete girder segments, with or without a cast-in-place slab, may be made longitudinally continuous for both permanent and transient loads with combinations of post-tensioning and/or reinforcement crossing the closure joints.

The width of a closure joint between precast concrete segments shall allow for the splicing of steel whose continuity is required by design considerations and the accommodation of the splicing of post-tensioning ducts. The width of a closure joint shall not be less than 12.0 in., except for joints located within a diaphragm, for which the width shall not be less than 4.0 in.

If the width of the closure joint exceeds 6.0 in., its compressive chord section shall be reinforced for confinement.

If the joint is located in the span, its web reinforcement, A_s/s , shall be the larger of that in the adjacent girders.

The face of the precast segments at closure joints shall be specified as either intentionally roughened to expose coarse aggregate or having shear keys in accordance with Article 5.12.5.4.2.

5.12.3.4.2c—Details of Match-Cast Joints

Match-cast joints for spliced precast girder bridges shall be detailed in accordance with Article 5.12.5.4.2.

5.12.3.4.2d—Joint Design

Stress limits for temporary concrete stresses in joints specified in Article 5.9.2.3.1 for segmentally constructed bridges shall apply at each stage of prestressing (pretensioning or post-tensioning). The concrete strength at the time the stage of prestressing is applied shall be substituted for f_{ci} in the stress limits.

Stress limits for concrete stresses in joints at the service limit state specified in Article 5.9.2.3.2 for segmentally constructed bridges shall apply. These stress limits shall also apply for intermediate load stages, with the concrete strength at the time of loading substituted for f'_c in the stress limits.

Resistance factors for joints specified in Article 5.5.4.2 for segmental construction shall apply.

The compressive strength of the closure joint concrete at a specified age shall be compatible with design stress limitations.

C5.12.3.4.2b

Where diaphragms are provided at closure joint locations, designers should consider extending the closure joint at the exterior girder beyond the outside face of the girder. Extending the closure joint beyond the face of the exterior girder also provides improved development of diaphragm reinforcement for bridges subject to extreme events.

The intent of the joint width requirement is to allow proper compaction of concrete in the cast-in-place closure joint. In some cases, narrower joints have been used successfully. Consolidation of concrete in a closure joint is enhanced when the joint is contained within a diaphragm. A wider closure joint may be used to provide more room to accommodate tolerances for potential misalignment of ducts within girder segments and misalignment of girder segments at erection.

The bottom flange near an interior support acts nearly as a column, hence the requirement for confinement steel.

The *AASHTO LRFD Bridge Construction Specifications* require vertical joints to be keyed. However, proper attention to roughened joint preparation is expected to ensure bond between the segments, providing better shear strength than shear keys.

C5.12.3.4.2c

One or more large shear keys may be used with spliced girders rather than the multiple small amplitude shear keys indicated in Article 5.12.5.4.2. The shear key proportions specified in Article 5.12.5.4.2 should be used.

5.12.3.4.3—Girder Segment Design

Stress limits for temporary concrete stresses in girder segments specified in Article 5.9.2.3.1 for other than segmentally constructed bridges shall apply at each stage of prestressing (pretensioning or post-tensioning) with due consideration for all applicable loads during construction. The concrete strength at the time the stage of prestressing is applied shall be substituted for f'_{ci} in the stress limits.

Stress limits for concrete stresses in girder segments at the service limit state specified in Article 5.9.2.3.2 for other than segmentally constructed bridges shall apply. These stress limits shall also apply for intermediate load stages, with the concrete strength at the time of loading substituted for f'_c in the stress limits.

Where girder segments are precast without prestressed reinforcement, the provisions of Article 5.6.7 shall apply until post-tensioning is applied.

Where variable depth girder segments are used, the effect of inclined compression shall be considered.

The potential for buckling of tall thin web sections shall be considered.

5.12.3.4.4—Post-Tensioning

Post-tensioning may be applied either before and/or after placement of deck concrete. Part of the post-tensioning may be applied to provide girder continuity prior to placement of the deck concrete, with the remainder placed after deck concrete placement.

The contract documents shall require that all post-tensioning tendons shall be fully grouted after stressing.

Prior to grouting of post-tensioning ducts, gross cross-section properties shall be reduced by deducting the area of ducts and void areas around tendon couplers.

Post-tensioning shall be shown on the contract documents according to the requirements of Article 5.12.5.3.10.

Where tendons terminate at the top of a girder segment, the contract documents shall require that duct openings be protected during construction to prevent debris accumulation and that drains be provided at tendon low points.

In the case of multistage post-tensioning, draped ducts for tendons to be tensioned before the slab concrete is placed and attains the minimum design concrete compressive strength f'_{ci} shall not be located in the slab.

Where some or all post-tensioning tendons are stressed after the deck concrete is placed, provisions shall be shown on the contract plans satisfying the provisions of Article 2.5.2.3 on maintainability of the deck.

C5.12.3.4.3

Segments of spliced precast girders shall preferably be pretensioned for dead load and all applicable construction loadings to satisfy temporary stress limits in the concrete.

Temporary construction loads must be considered where these loads may contribute to critical stresses in girder segments at an intermediate stage of construction, such as when the deck slab is placed when only a portion of the total prestress has been applied. Temporary construction loads are specified in the *AASHTO Guide Design Specifications for Bridge Temporary Works* (2017).

Because gravity loads induce compression in the bottom flange of girders at support locations, the vertical force component from inclined flexural stresses in a haunched girder segment generally acts to reduce the applied shear. Its effect can be accounted for in the same manner as the vertical component of the longitudinal prestressing force, V_p . However, the reduction of the vertical shear force from this effect is usually neglected.

C5.12.3.4.4

Where some or all post-tensioning is applied after the deck concrete is placed, fewer post-tensioning tendons and a lower concrete strength in the closure joint may be required. However, deck replacement, if necessary, is difficult to accommodate with this construction sequence. Where all of the post-tensioning is applied before the deck concrete is placed, a greater number of post-tensioning tendons and a higher concrete strength in the closure joint may be required. However, in this case, the deck can be replaced if necessary. See Castrodale and White (2004) for more information.

See Article 5.9.5.3 for post-tensioning coupler requirements.

Where tendons terminate at the top of the girder, blockouts and pourbacks in the deck slab are required for access to the tendons and anchorages. While this arrangement has been used, it is preferable to anchor all tendons at the ends of girders. Minimizing or eliminating deck slab blockouts by placing anchorages at ends of girders reduces the potential for water seepage and corrosion at the post-tensioning tendon anchors.

This provision is to ensure that ducts as yet unsecured by concrete will not be used for active post-tensioning.

See Article 5.14.5 for deck protection systems.

5.12.3.5—Cast-in-Place Box Girders and T-Beams

5.12.3.5.1—Flange and Web Thickness

5.12.3.5.1a—Top Flange

The thickness of top flanges serving as deck slabs shall not be less than the greatest of the following:

- that determined in Section 9;
- that required for anchorage and cover for transverse prestressing, if used; and
- the clear span between fillets, haunches, or webs divided by 20, unless transverse ribs at a spacing equal to the clear span are used or transverse prestressing is provided.

5.12.3.5.1b—Bottom Flange

The bottom flange thickness shall be not less than the greatest of the following:

- 5.5 in.;
- the distance between fillets or webs of nonprestressed girders and beams divided by 16;
- the clear span between fillets, haunches, or webs for prestressed girders divided by 30, unless transverse ribs at a spacing equal to the clear span are used.

5.12.3.5.1c—Web

The thickness of webs shall be determined by requirements for shear, torsion, concrete cover, and placement of concrete.

Changes in girder web thickness shall be tapered for a minimum distance of 12.0 times the difference in web thickness.

5.12.3.5.2—Reinforcement

5.12.3.5.2a—Deck Slab Reinforcement Cast-in-Place in T-Beams and Box Girders

The reinforcement in the deck slab of cast-in-place T-beams and box girders may be determined by either the traditional or the empirical design methods specified in Section 9.

Where the deck slab does not extend beyond the exterior web, at least one third of the bottom layer of the transverse reinforcement in the deck slab shall be extended into the exterior face of the outside web and anchored by a standard 90-degree hook. If the slab extends beyond the exterior web, at least one-third of the bottom layer of the transverse reinforcement shall be extended into the slab overhang and shall have an anchorage beyond the exterior face of the web not less in resistance than that provided by a standard hook.

C5.12.3.5.1c

For adequate field placement and consolidation of concrete, the minimum web thickness specified in Article 5.12.5.3.11b should be considered. For girders over about 8.0 ft in depth, these dimensions should be increased to compensate for the increased difficulty of concrete placement.

5.12.3.5.2b—Bottom Slab Reinforcement in Cast-in-Place Box Girders

A uniformly distributed reinforcement of 0.4 percent of the flange area shall be placed in the bottom slab parallel to the girder span, either in single or double layers. The spacing of such reinforcement shall not exceed 18.0 in.

A uniformly distributed reinforcement of 0.5 percent of the cross-sectional area of the slab, based on the least slab thickness, shall be placed in the bottom slab transverse to the girder span. Such reinforcement shall be distributed over both surfaces with a maximum spacing of 18.0 in. All transverse reinforcement in the bottom slab shall be extended to the exterior face of the outside web in each group and shall be anchored by a standard 90-degree hook.

5.12.4—Diaphragms

Diaphragms, subjected primarily to shear and torsion and whose depth is large relative to their span shall be analyzed and designed by either the STM specified in Article 5.8.2 or legacy methods in Article 5.8.4.

Unless otherwise specified, diaphragms shall be provided at abutments, piers, and hinge joints to resist applied forces and transmit them to points of support.

Intermediate diaphragms may be used between beams in curved systems or where necessary to provide torsional resistance and to support the deck at points of discontinuity or at right angle points of discontinuity or at angle points in girders.

For spread box beams having an inside radius less than 800 ft, intermediate diaphragms shall be used.

5.12.5—Segmental Concrete Bridges

5.12.5.1—General

The requirements specified herein shall supplement the requirements of other Sections of these Specifications for concrete structures designed to be constructed by the segmental method.

C5.12.3.5.2b

This provision is intended to apply to both reinforced and prestressed boxes.

In certain types of construction, end diaphragms may be replaced by an edge beam or a strengthened strip of slab made to act as a vertical frame with the beam ends. Such types are low I-beams and double-T beams. These frames should be designed for wheel loads.

The diaphragms should be essentially solid, except for access openings and utility holes, where required.

For curved bridges, the need for and the required spacing of diaphragms depends on the radius of curvature and the proportions of the webs and flanges. Some references have found that interior diaphragms contributed very little to the global behavior of concrete box girder bridges.

C5.12.5.1

For segmental construction, superstructures of single- or multiple-cell box sections are generally used. Segmental construction includes construction by free cantilever, span-by-span, incremental launching, or other methods using either precast or cast-in-place concrete segments which are connected together to produce either continuous or simple spans.

Bridges utilizing beam-type sections may also be constructed using segmental construction techniques. Such bridges, which are referred to as spliced precast girder bridges in these Specifications, are considered to be a special case of conventional concrete bridges. The design of such bridges is covered in Article 5.12.3.4.

The span length of bridges considered by these Specifications ranges to 800 ft. Bridges supported by stay cables are not specifically covered in this article,

The method and schedule of construction assumed for the design shall be shown in the contract documents. Temporary supports required prior to the time the structure, or component thereof, is capable of supporting itself including loads and sequence in construction, shall also be shown in the contract documents.

The contract documents shall indicate alternative methods of construction permitted and the Contractor's responsibilities if such methods are chosen. Any changes by the Contractor in the construction method or in the design shall comply with the requirements of Article 5.12.5.5.

5.12.5.2—Analysis of Segmental Bridges

5.12.5.2.1—General

The analysis of segmentally constructed bridges shall conform to the requirements of Section 4 and those specified herein.

5.12.5.2.2—Construction Analysis

For the analysis of the structure during the construction stage, the construction load combinations, stresses, and stability considerations shall be as specified in Article 5.12.5.3.

5.12.5.2.3—Analysis of the Final Structural System

The final structural system shall be analyzed for redistribution of construction-stage force effects due to internal deformations from creep and shrinkage and changes in support and restraint conditions, including accumulated locked-in force effects resulting from the construction process.

although many of the specification provisions are also applicable to them.

The method of construction and any required temporary support is of paramount importance in the design of segmental concrete bridges. Such considerations often govern final conditions in the selection of section dimensions and reinforcing and/or prestressing.

For segmentally constructed bridges, designs should and generally do allow the Contractor some latitude in choice of construction methods. To ensure that the design features and details to be used are compatible with the proposed construction method, it is essential that the Contractor is required to prepare working drawings and calculations based on his choice of methods for review and approval by the Engineer before work begins.

C5.12.5.2.3

Results of analyses of a segmental concrete superstructure that has values of creep coefficient of 1, 2, and 3 and that uses both the ACI 209 and CEB-FIP (CEB, 1990) creep models, have been published (AASHTO, 1999). Final stresses were essentially unchanged for creep coefficients of 1, 2, and 3 using the ACI 209 creep provisions. Although the analyses with the CEB-FIP creep model show somewhat more variation in final stresses, the range of stresses is still small for a large variation in creep coefficients. The selection of the ACI 209 or CEB-FIP creep model has a larger impact on the final stress values than the creep coefficients. However, it is doubtful that the full range of stresses reflected in the six analyses described would be of practical significance with respect to the performance of the structure.

Because the creep coefficient will be known or determined with reasonable accuracy under the requirements of these Specifications, analysis using a single value of the creep coefficient is considered satisfactory, and use of low and high values of the creep coefficient in analysis is generally considered unnecessary. This is not intended to imply that creep values should not be determined accurately because these values do have a significant impact on the prestress losses, deflections, and axial shortening of the structure.

Joints in segmental girders made continuous by unbonded tendons shall be investigated for the simultaneous effect of axial force, moment, and shear that may occur at a joint. These force effects, the opening of the joint, and the remaining contact surface between the components shall be determined by global consideration of strain and deformation. Shear shall be assumed to be transmitted through the contact area only.

5.12.5.3—Design

5.12.5.3.1—Loads

In addition to the loads specified in Section 3, the construction loads specified in Articles 5.12.5.3.2 through 5.12.5.3.4 shall be considered.

5.12.5.3.2—Construction Loads

Construction loads and conditions that are assumed in the design and that determine section dimensions, camber, and reinforcing and/or prestressing requirements shall be shown as maximum allowed in the contract documents. In addition to erection loads, any required temporary supports or restraints shall be defined as to magnitude or included as part of the design. The acceptable closure forces due to misalignment corrections shall be stated. Due allowance shall be made for all effects of any changes of the statical structural scheme during construction and the application, changes, or removal of the assumed temporary supports of special equipment, taking into account residual force effects, deformations, and any strain-induced effects.

The following construction loads shall be considered:

<i>DC</i>	=	weight of the supported structure (kip)
<i>DIFF</i>	=	differential load: applicable only to balanced cantilever construction taken as two percent of the dead load applied to one cantilever (kip)
<i>DW</i>	=	superimposed dead load if present at the stage of erection under consideration (kip or klf)
<i>CLL</i>	=	distributed construction live load: an allowance for miscellaneous items of plant, machinery, and other equipment, apart from the major specialized erection equipment; taken as 0.010 ksf of deck area; in cantilever construction, this load is taken as 0.010 ksf on one cantilever and 0.005 ksf on the other; for bridges built by incremental launching, this load may be neglected (ksf)
<i>CEQ</i>	=	specialized construction equipment: the load from segment or material delivery trucks, or both, and any special equipment, including a formtraveler launching gantry, beam and winch, truss, or similar major

Joining components with unbonded tendons may permit the opening of unreinforced joints at or close to strength limit states. The Designer should review the structural consequences of such joint openings.

C5.12.5.3.2

Construction loads comprise all loadings arising from the Designer's anticipated system of temporary supporting works and/or special erection equipment to be used in accordance with the assumed construction sequence and schedule.

Construction loads and conditions frequently determine section dimensions and reinforcing and/or prestressing requirements in segmentally constructed bridges. It is important that the Designer shows these assumed conditions in the contract documents.

These provisions are not meant to be limitations on the Contractor as to the means that may be used for construction. Controls are essential to prevent damage to the structure during construction and to ensure adequacy of the completed structure. It is also essential for the bidders to be able to determine if their equipment and proposed construction methods can be used without modifying the design or the equipment.

The contract documents should require the Engineer's approval of any changes in the assumed erection loadings or conditions.

Construction loads may be imposed on opposing cantilever ends by use of the formtraveler, diagonal alignment bars, a jacking tower, or external weights. Cooling of one cantilever with water has also been used to provide adjustment of misalignment. Any misalignment of interior cantilevers should be corrected at both ends before constructing either closure. The frame connecting cantilever ends at closure pours should be detailed to prevent differential rotation between cantilevers until the final structural connection is complete. The magnitude of closure forces should not induce stresses in the structure in excess of those tabulated in Table 5.12.5.3.3-1.

The load, *DIFF*, allows for possible variations in cross-section weight due to construction irregularities.

For very gradual lifting of segments, where the load involves small dynamic effects, the dynamic load *IE* may be taken as ten percent of the lifted weight.

		auxiliary structure and the maximum loads applied to the structure by the equipment during the lifting of segments (kip)
<i>IE</i>	=	dynamic load from equipment: determined according to the type of machinery anticipated (kip)
<i>CLE</i>	=	longitudinal construction equipment load: the longitudinal load from the construction equipment (kip)
<i>U</i>	=	segment unbalance: the effect of any out-of-balance segments or other unusual conditions as applicable; applies primarily to balanced cantilever construction but may be extended to include any unusual lifting sequence that may not be a primary feature of the generic construction system (kip)
<i>WS</i>	=	horizontal wind load on structures in accordance with the provisions of Section 3 The wind speed associated with load combinations e and f in Table 5.12.5.3.3-1 and the wind speed associated with load combinations c and d in Table 5.12.5.3.3-1 shall be as determined by the Owner (ksf)
<i>WE</i>	=	horizontal wind load on equipment; taken as 0.1 ksf of exposed surface (ksf)
<i>WUP</i>	=	wind uplift on cantilever: 0.005 ksf of deck area for balanced cantilever construction applied to one side only, unless an analysis of site conditions or structure configuration indicates otherwise (ksf)
<i>A</i>	=	static weight of precast segment being handled for precast cantilever construction or the empty weight of the form-traveler being utilized for cast-in-place cantilever construction (kip)
<i>AI</i>	=	dynamic response due to accidental release or application of a precast segment load, empty form-traveler load or other sudden application of an otherwise static load to be added to the dead load; in lieu of a dynamic analysis, may be taken as 100 percent of load <i>A</i> (kip)
<i>CR</i>	=	creep effects, in accordance with Article 5.12.5.3.6
<i>SH</i>	=	shrinkage, in accordance with Article 5.12.5.3.6
<i>T</i>	=	thermal: the sum of the effects due to uniform temperature variation, <i>TU</i> , and temperature gradients, <i>TG</i> (°F)

5.12.5.3.3—Construction Load Combinations at the Service Limit State

Flexural tension and principal tension stresses shall be determined at service limit states as specified in Table 5.12.5.3.3-1, for which the following notes apply:

- Note 1: equipment not working:

The following information is based on some past experience and could be considered for preliminary design. Form-travelers for cast-in-place segmental construction for a typical two-lane bridge with 15.0 to 16.0 ft segments may be estimated to weigh 160 to 180 kips. The weight of form-travelers for wider double-celled box sections may range up to approximately 280 kips. Consultation with contractors or subcontractors experienced in free cantilever construction, with respect to the specific bridge geometry under consideration, is recommended to obtain a design value for form-traveler weight.

Using wind speeds of 0.75 of the speed used for the in-service Strength III limit state for load combinations c and d and 70 mph for load combinations e and f is a reasonable approximation of wind loads that would have resulted from past practice using the AASHTO *LRFD Bridge Design Specifications* prior to the change from fastest mile wind speed to three-second gust wind speed. ASCE 37 can also help give guidance for wind loads during construction.

Cast-in-place segments are typically supported by form-travelers. Accidental release may involve the release of the empty form-traveler. Accidental release may also involve failure of the supports for the bottom soffit form during segment casting, thereby releasing the bottom slab form and working platform, as well as the bottom slab and web concrete. In the worst case, accidental release may involve failure of the entire form-traveler and all newly cast segment concrete. The weight of the empty form-traveler is the minimum load that should be included in *AI*. Note that using 100 percent of the weight of the empty form-traveler for *AI* is a practice that has been successfully utilized in France without collapse of a cantilever. Owners seeking a further reduction of risk could consider including the weight of some segment concrete in *A* and *AI*.

For precast segments being lifted by a beam and winch or deck-mounted crane, and cast-in-place segments being supported by form-travelers, the dynamic effect of an accidental release is an upward rebound. For precast segments being lifted by a ground-based crane where the segment could be above the cantilever, the dynamic effect is a downward impact force from the segment being suddenly released during lifting.

C5.12.5.3.3

Table 5.12.5.3.3-1 was developed primarily for balanced cantilever construction but provides a reasonable basis for load combinations for other segmental construction methods. When applied to construction methods other than balanced cantilever

Table 5.12.5.3.3-1—Load Factors and Tensile Stress Limits for Construction Load Combinations

5.12.5.3.4—Construction Load Combinations at Strength and Extreme Event Limit States

5.12.5.3.4a—Construction Load Combinations at the Strength Limit State

The factored resistance of a component shall be determined using resistance factors specified in Article 5.5.4.2. The following components shall be evaluated for construction loads at the Strength I, III, and V limit states:

- Prestressed or conventionally reinforced substructures
- Prestressed or conventionally reinforced segmental superstructures

The Strength I, III, and V load combinations from Table 3.4.1-1 shall apply with the load factors in the table and as modified by this Article. The loads *DIFF*, *CEQ*, and *IE* shall be included and factored with γ_p for *DC*. The load *WUP* shall be included with *WS*. The load *CLL* shall be included and used in place of *LL*. The load *WE* shall be included with load factors of 0.9 and 0.4 for the Strength III and Strength V load combinations, respectively. The wind speeds for *WS* associated with the Strength III and Strength V load combinations shall be as determined by the Owner.

5.12.5.3.4b—Construction Load Combinations at the Extreme Event Limit State

In accordance with Article 1.3.2.1, the resistance factor for concrete design shall be 1.0. The loads *DIFF* and *CLL* shall be placed to maximize the force effects.

- For maximum force effects:

$$\Sigma YQ = 1.1(DC + DIFF) + 1.3(CEQ + CLL) + A + AI \quad (5.12.5.3.4b-1)$$

- For minimum force effects:

$$\Sigma YQ = DC + DIFF + CEQ + CLL + A + AI \quad (5.12.5.3.4b-2)$$

In addition to the superstructure, the following substructure elements shall consider the dynamic response, *AI*:

- Temporary supports and their foundations.
- Piers, including the pier to footing or pier to monoshaft connection.
- Above grade or buried footings. The design shall be based on pile or shaft force effects resulting from an analysis of the dynamic response, regardless of whether the static geotechnical resistance of the piles or shafts is exceeded.

C5.12.5.3.4a

Using a load factor of 1.25 for construction equipment loads for segmental construction, such as erection gantries, cranes supported by the structure, and segment transporters is reasonable as opposed to the 1.5 load factor specified in Article 3.4.2 for construction loads. This is because construction equipment loads are well known or included in the plans for the construction method assumed for design. Smaller miscellaneous construction loads are included in the *CLL* allowance.

Using load factors of 1.0 with wind speeds of 0.95 of the speed used for the in-service Strength III limit state for the construction Strength III load combination, and 75 mph for the construction Strength V load combination are reasonable approximations of wind loads that would have resulted from past practice using the AASHTO LRFD Bridge Design Specifications prior to the change from fastest mile wind speed to three-second gust wind speed. ASCE 37 can also help give guidance for wind loads during construction.

C5.12.5.3.4b

The construction load combinations evaluated at the extreme event limit state are intended to address a low probability event. This extreme event limit state evaluation does not replace the evaluation of construction loads under the service limit state or strength limit state.

- Piles and shafts supporting footings where the ground or mudline is less than one diameter of a foundation element above the bottom of footing, regardless of whether the static geotechnical resistance of the piles or shafts is exceeded. The structural resistance of the piles or shafts shall be checked from the bottom of the footing to the first points of maximum moment and shear below the ground or mudline.
- The structural resistance of mon shafts, even if below the ground or mudline, shall be checked to the first points of maximum moment and shear below the ground or mudline.

5.12.5.3.5—Thermal Effects During Construction

Thermal effects that may occur during the construction of the bridge shall be considered.

The temperature setting variations for bearings and expansion joints shall be stated in the contract documents.

5.12.5.3.6—Creep and Shrinkage

Creep and shrinkage shall be determined in accordance with Article 5.4.2.3. Forces and stresses shall be determined for redistribution of restraint stresses developed by creep and shrinkage deformations that are based on the assumed construction schedule as stated in the contract documents.

For determining the final post-tensioning forces, prestress losses shall be calculated for the construction schedule stated in the contract documents.

C5.12.5.3.5

The provisions of Article 3.12 relate to annual temperature variations and should be adjusted for the actual duration of superstructure construction as well as for local conditions.

Transverse analysis for the effects of differential temperature outside and inside box girder sections is not generally considered necessary. However, such an analysis may be necessary for relatively shallow bridges with thick webs. In that case, a $\pm 10.0^\circ\text{F}$ temperature differential is recommended.

C5.12.5.3.6

A variety of computer programs and analytical procedures have been published to determine creep and shrinkage effects in segmental concrete bridges.

Creep strains and prestress losses that occur after closure of the structure cause a redistribution of the force effects.

For permanent loads, the behavior of segmental bridges after closure may be approximated by use of an effective modulus of elasticity, E_{eff} , which may be calculated as:

$$E_{eff} = \frac{E_c}{\Psi(t, t_i) + 1} \quad (\text{C5.12.5.3.6-1})$$

where:

$\Psi(t, t_i)$ = creep coefficient at time t for loading applied at time t_i

A comprehensive series of equations for evaluating the time-related effects of creep and shrinkage is presented in the ACI Committee 209 report, *Prediction of Creep, Shrinkage and Temperature Effects in Concrete Structures* (ACI 209, 1982). A procedure based on graphical values for creep and shrinkage parameters is presented in the *CEB-FIP Model Code* (CEB, 1990). Comparisons of the effects of application

of the ACI and CEB provisions are presented in the Appendix of the first edition of the *AASHTO Guide Specifications for Design and Construction of Segmental Concrete Bridges* (AASHTO, 1999) (Ketchum, 1986).

Bryant and Vadhanavikkit (1987) suggest that the ACI 209 predictions underestimate the creep and shrinkage strains for the large-scale specimens used in segmental bridges. The ACI 209 creep predictions were consistently about 65 percent of the experimental results in these tests. The report suggests modifications of the ACI 209 equations based on the size or thickness of the members.

5.12.5.3.7—*Prestress Losses*

The applicable provisions of Article 5.9.3 shall apply.

C5.12.5.3.7

The friction and wobble coefficients in Article 5.9.3.2.2 for galvanized duct were developed for conventional cast-in-place box girder bridges based on job-site tests of various sizes and lengths of tendons. The values are reasonably accurate for tendons comprised of 12 strands of 0.5-in. diameter in a 2.625-in. diameter galvanized metal sheathing. Tests and experience indicate that the values are conservative for larger tendons and duct diameters. However, experience with segmental concrete bridges to date has often indicated higher friction and wobble losses due to movement of ducts during concrete placement and misalignment at segment joints. For this reason, in-place friction tests are recommended at an early stage in major projects as a basis for modifying friction and wobble loss values. No reasonable values for friction and wobble coefficients can be recommended to account for gross duct misalignment problems. As a means of compensating for high friction and wobble losses or provisional post-tensioning tendons as well as for other contingencies, additional ducts are required in accordance with Article 5.12.5.3.9.

5.12.5.3.8—*Alternative Shear Design Procedure*

5.12.5.3.8a—*General*

Where it is reasonable to assume that plane sections remain plane after loading, the provisions of Article 5.7.3 or the alternative provisions of the Articles herein may be used for the design of segmental post-tensioned concrete box girder bridges for shear and torsion.

The applicable provisions of Articles 5.7.1, 5.7.2, and 5.7.4 may apply, as modified by the provisions herein.

Discontinuity regions (where the plane sections assumption of flexural theory is not applicable) shall be designed using the provisions herein and the STM of Article 5.8.2. The provisions of Article 5.8.4 shall apply to special discontinuity regions such as deep beams, brackets and corbels, as appropriate.

The values of compressive strength of concrete for use in design using these provisions shall be in accordance with Article 5.7.2.1.

C5.12.5.3.8a

Discontinuity regions where the plane sections assumption of flexural theory is not applicable include regions adjacent to abrupt changes in cross-sections, openings, dapped ends, regions where large concentrated loads, reactions, or post-tensioning forces are applied or deviated, diaphragms, deep beams, corbels, or joints.

The design yield strength of transverse shear or torsion reinforcement shall be in accordance with Article 5.7.2.7.

5.12.5.3.8b—Loading

Where the alternative provisions for design for shear and torsion permitted herein are invoked, the shear component of the primary effective longitudinal prestress force acting in the direction of the applied shear being examined, V_p , shall be added to the load effect, with a load factor of 1.0.

The effects of applied factored torsional moments, T_u , shall be considered in the design when their magnitude exceeds the value specified in Article 5.7.2.1.

C5.12.5.3.8b

This load effect should only be added to the box girder analysis and not transferred into the substructure. Some designers prefer to add this primary prestress force shear component to the resistance side of the equation.

For members subjected to combined shear and torsion, the torsional moments produce shear forces in different elements of the structure that, depending on the direction of torsion, may add to or subtract from the shear force in the element due to vertical shear. Where it is required to consider the effects of torsional moments, the shear forces from torsion need to be added to those from the vertical shear when determining the design shear force acting on a specific element. The possibility of the torsional moment reversing direction should be investigated.

5.12.5.3.8c—Nominal Shear Resistance

In lieu of the provisions of Article 5.7.3, the provisions herein may be used to determine the nominal shear and torsion resistance of post-tensioned concrete box girders in regions where it is reasonable to assume that plane sections remain plane after loading.

Transverse reinforcement shall be provided when $V_u > 0.5\phi V_c$, where V_c is computed by Eq. 5.12.5.3.8c-3.

The factored nominal shear resistance, ϕV_n , shall be greater than or equal to V_u .

The applied factored shear, V_u , in regions near supports may be computed at a distance $h/2$ from the support when the support reaction, in the direction of the applied shear, introduces compression into the support region of the member and no concentrated load occurs within a distance, h , from the face of the support.

The nominal shear resistance, V_n , shall be determined as the lesser of the following:

$$V_n = V_c + V_s \quad (5.12.5.3.8c-1)$$

$$V_n = 0.379\lambda\sqrt{f'_c} b_v d \quad (5.12.5.3.8c-2)$$

in which:

$$V_c = 0.0632K\lambda\sqrt{f'_c} b_v d \quad (5.12.5.3.8c-3)$$

$$V_s = \frac{A_v f_y d}{s} \quad (5.12.5.3.8c-4)$$

C5.12.5.3.8c

The expression for V_c has been checked against a wide range of test data and has been found to be a conservative expression. Additional background on the shear and torsion provisions in this Article can be found in Ramirez and Breen (1991).

The maximum nominal shear resistance in Eq. 5.7.3.3-2 of Article 5.7.3 is higher than that in Article 5.12.5.3.8c. This difference increases as the compressive strength of the concrete increases. The limit in Eq. 5.12.5.3.8c-2 is similar to that in ACI 318-14 building code provisions and has been found to be unnecessarily conservative (Rangan, 1991) (Tantipidok et al., 2011).

Eq. 5.12.5.3.8c-4 is based on an assumed 45-degree truss model.

Eqs. 5.12.5.3.8c-3 and 5.12.5.3.8c-6 are only used to establish appropriate concrete section dimensions.

$$K = \sqrt{1 + \frac{f_{pc}}{0.0632\lambda\sqrt{f'_c}}} \leq 2.0 \quad (5.12.5.3.8c-5)$$

Where the effects of torsion are required to be considered by Article 5.7.2.1, the cross-sectional dimensions shall be such that:

$$\left(\frac{V_u}{b_v d} \right) + \left(\frac{T_u}{2 A_o b_e} \right) \leq 0.474 \lambda \sqrt{f'_c} \quad (5.12.5.3.8c-6)$$

where:

- λ = concrete density modification factor, as specified in Article 5.4.2.8
- f'_c = compressive strength of concrete for use in design (ksi)
- b_v = effective web width taken as the total minimum width of all webs within the depth d adjusted for the effect of openings or ducts, as specified in Article 5.7.2.8.
- d = $0.8h$ or the distance from the extreme compression fiber to the centroid of the prestressing reinforcement, whichever is greater (in.)
- A_v = total area of transverse reinforcing in all webs in the cross-section within a distance, s (in.²)
- s = spacing of stirrups (in.)
- f_{pc} = unfactored compressive stress in concrete after prestress losses have occurred either at the centroid of the cross-section resisting transient loads or at the junction of the web and flange where the centroid lies in the flange (ksi)
- V_u = factored design shear including any normal component from the primary prestressing force (kip)
- T_u = applied factored torsional moment (kip-in.)
- A_o = area enclosed by shear flow path, including any area of holes therein (in.²)
- b_e = the effective thickness of the shear flow path of the elements making up the space truss model resisting torsion, calculated in accordance with Article 5.7.2.1 (in.)
- ϕ = resistance factor for shear, specified in Article 5.5.4.2

5.12.5.3.8d—Torsional Reinforcement

Where consideration of torsional effects is required by Article 5.7.2.1 torsion reinforcement shall be provided, as specified herein. This reinforcement shall be in addition to the reinforcement required to resist the factored shear, as specified in Article 5.12.5.3.8c, flexure and axial forces that may act concurrently with the torsion.

The longitudinal and transverse reinforcement required for torsion shall satisfy:

C5.12.5.3.8d

Use of reinforcement with f_y greater than 75.0 ksi has not been verified by tests.

$$T_u \leq \phi T_n \quad (5.12.5.3.8d-1)$$

The nominal torsional resistance from transverse reinforcement shall be based on a truss model with 45-degree diagonals and shall be computed as:

$$T_n = \frac{2A_o A_t f_y}{s} \quad (5.12.5.3.8d-2)$$

The minimum additional longitudinal reinforcement for torsion, A_t , shall satisfy:

$$A_t \geq \frac{T_u p_h}{2\phi A_o f_y} \quad (5.12.5.3.8d-3)$$

where:

- T_u = applied factored torsional moment (kip-in.)
- ϕ = resistance factor for shear, specified in Article 5.5.4.2
- A_o = area enclosed by shear flow path, including any area of holes therein (in.²)
- A_t = total area of transverse torsion reinforcing in the exterior web and flange (in.²)
- f_y = yield strength of additional longitudinal reinforcement (ksi)
- A_t = total area of longitudinal torsion reinforcement in a box girder (in.²)
- p_h = perimeter of the polygon defined by the centroids of the longitudinal chords of the space truss resisting torsion. p_h may be taken as the perimeter of the centerline of the outermost closed stirrups (in.)

A_t shall be distributed around the outer-most webs and top and bottom slabs of the box girder in accordance with Article 5.12.5.3.8e. At least one bar or tendon shall be placed in the corners of the stirrups. Where corner bars are used, they shall not be less than 0.625 in.

In determining the required amount of longitudinal reinforcement, the beneficial effect of longitudinal prestressing is taken into account by considering the longitudinal prestressing force in excess of that required for concurrent flexure and shear as an equivalent area of reinforcement.

The total area of transverse reinforcing, A_t , must be placed in each exterior web and flange that forms the closed section.

Unlike solid sections, when designing the webs of segmental bridges, the shear and torsion reinforcement should be directly added together. Reinforcement for transverse bending in the webs and other box girder elements should be accounted for in the total reinforcement demand. Standard practice for typical segmental highway bridges is to combine the shear and torsion reinforcement, and transverse bending reinforcement in each box girder element so that the total reinforcement on each face of each web or flange exceeds the greater of:

$$\bullet \quad 1.0(A_{sv} + A_{st}) + 0.5A_{sb} \quad (C5.12.5.3.8d-1)$$

$$\bullet \quad 0.5(A_{sv} + A_{st}) + 1.0A_{sb} \quad (C5.12.5.3.8d-2)$$

where:

- A_{sv} = area of required shear reinforcement for one face of a web within a distance, s (in.²)
- A_{st} = area of required torsion reinforcement for one face of an exterior web or flange within a distance, s (in.²)
- A_{sb} = area of required reinforcement due to transverse bending for one face of a web or flange within a distance, s (in.²)

The equations above acknowledge that the maximum shear and torsion effect is unlikely to occur concurrently with maximum transverse bending. However, the engineer must consider if this condition is applicable to the structure in design. Examples where direct combination of the reinforcement are applicable include single-lane ramp structures and transit structures.

5.12.5.3.9b—Bridges with Internal Ducts

Provisional duct or anchorage capacity shall accommodate increases to both positive moment and negative moment post-tensioning forces. The increases shall be taken as not less than five percent of the total post-tensioning forces specified in the contract documents.

For continuous bridges, positive moment force adjustment need only be provided for the middle 50 percent of each span.

Provisional capacity shall be uniformly distributed to each web and located symmetrically about the bridge centerline. Anchorages shall be distributed uniformly at three-segment intervals along the length of the bridge.

Utilized and unutilized provisional ducts shall be grouted at the same time as other ducts in the span.

5.12.5.3.9c—Provision for Future Load

Provision shall be made for installation and stressing access and for anchorage attachments, pass-through openings, and deviation saddle attachments to permit future addition of corrosion-protected unbonded external tendons located inside the box section symmetrically about the bridge centerline. Diaphragm and deviation saddles shall be designed to accommodate the forces from the future tendons. At a minimum one future tendon for exterior webs and two future tendons for interior webs shall be provided. These tendons shall have a minimum size equivalent to 12-06" diameter strand tendons. The future tendons shall satisfy one of the following requirements:

- Future tendons shall provide a post-tensioning force of not less than ten percent of the primary positive moment and negative moment post-tensioning forces.
- Future tendons shall be designed to increase the superstructure resistance for flexure, shear, and torsion for the in-service Strength I, Service I and Service III load combinations to accommodate the combined effect of the following load increases:
 - Ten percent DW
 - Ten percent bridge railing dead load
 - Ten percent $LL+I$
 - Ten percent CR and SH

Any extra design resistance in the original design can be utilized to resist the specified load increases, such that the initial and future post-tensioning together meet the increased load requirements.

C5.12.5.3.9b

Provisional post-tensioning duct and/or anchorage capacity permit the introduction of additional prestressing force to compensate for installation or stressing problems that might arise during construction.

Excess capacity may be provided by use of oversize ducts and oversize anchorage hardware at selected anchorage locations well-distributed along the length of the bridge.

The purpose of grouting unused ducts is to prevent entrapment of water in the ducts.

C5.12.5.3.9c

This provides for future addition of external unbonded post-tensioning tendons.

The first requirement specifies an addition of future tendons to provide for a force of ten percent of the primary positive moment and negative moment post-tensioning forces and does not require any additional analysis.

The second requirement provides for a refinement of the future post-tensioning system by designing for a ten percent increase in the specified loads. Relative to the first option, this refinement allows for a reduction in future post-tensioning forces in regions where there is already extra capacity. An example is a balanced cantilever bridge constructed with form-travelers or beam and winches. The post-tensioning required to support the free cantilevers along with the equipment loads can be more than what is required for the in-service structure. Therefore, the future post-tensioning tendons for negative moment at the piers required to resist specified load increases can possibly be reduced from a ten percent increase in the negative post-tensioning force.

Typically, future post-tensioning tendons are draped external tendons that are close to the bottom slab near midspan and anchor in the pier diaphragms as high as possible. The tendons typically lap through the pier diaphragms with anchorages located on opposite sides of the diaphragm. Provision for larger amounts of post-tensioning might be developed, as necessary, to carry specific amounts of additional load as considered appropriate for the structure.

5.12.5.3.10—Plan Presentation

Contract documents shall include description of one construction method upon which the design is based. Contract drawings shall be detailed according to the provisions of *AASHTO LRFD Bridge Construction Specifications*, Section 10.

The concrete cross-section shall be proportioned to accommodate an assumed post-tensioning system, reinforcement, and all other embedded items. The concrete cross-section should also accommodate comparable anchorage sizes of competitive post-tensioning systems, unless noted otherwise on the plans.

5.12.5.3.11—Box Girder Cross-Section Dimensions and Details

5.12.5.3.11a—Minimum Flange Thickness

Top and bottom flange thickness shall not be less than all of the following:

- Unless transverse ribs spaced equal to the clear span between webs or haunches are provided:
 - $1/30$ of the clear span between webs where no haunches are present in the flange span, or;
 - $1/30$ of the span between the thinner ends of the haunches where haunches are present in the flange span.
- Top flange thickness shall not be less than 9.0 in. in anchorage zones where transverse post-tensioning is used and 8.0 in. beyond anchorage zones or for pretensioned slabs.

C5.12.5.3.10

Integrated drawings utilizing the assumed system should be defined to a scale and quality required to confirm elimination of interferences by all items embedded in the concrete.

Congested areas of post-tensioned concrete structures can easily be identified on integrated drawings using an assumed post-tensioning system. Such areas should include, but are not necessarily limited to, anchorage zones, diaphragms, deviators, blisters and other areas containing embedded items for the assumed post-tensioning system, and areas where post-tensioning ducts deviate both in the vertical and transverse directions. For curved structures, conflicts between webs and external tendons are possible. A check should be made to identify conflicts between future post-tensioning tendons and permanent tendons, and to provide for the necessary clearances in the design details to accommodate the post-tensioning jacks.

C5.12.5.3.11a

Top and bottom flanges for box girder sections may need to be thickened for structural reasons, such as transverse flexure, longitudinal flexure and longitudinal interface shear considerations. They may also need to be thickened to accommodate ducts, anchorages or other post-tensioning hardware. To save concrete and reduce weight, linear haunches at the webs may be utilized in lieu of thickening the entire slab. The length and amount of thickening for the haunches shall be determined by analysis and detailing considerations.

Typical haunch lengths are 20–25 percent of the total span between the webs, or longer, as required to accommodate post-tensioning hardware. The minimum amount of thickening that is typically utilized for haunches is 3.0 in. for the bottom flange, 5.0 in. for the top flange.

Where the clear span between the faces of webs is 15.0 ft or larger, transverse prestressing of the top deck is typically utilized. However, prestressing may also be utilized to improve deck durability (regardless of span length) at the Owner's discretion. To ensure that these benefits are realized, Owners need to ensure that project specifications explicitly state when transverse prestressing of the deck is required for other than structural purposes.

Transverse deck prestressing is typically accomplished through post-tensioning, although pretensioning has been utilized in the past. Strands for transverse pretensioning are limited to 0.6 in. diameter or less, consistent with other Articles in these Specifications.

For most existing segmental bridges, the cantilever length of the top flange is less than 0.60 of the interior clear span of the top flange. When the cantilever exceeds 0.45 of the interior span, designers should consider investigating top flange deflections during casting and erection and the need for partial post-tensioning of the top flange for geometry control.

5.12.5.3.11b—Minimum Web Thickness

The following minimum values shall apply, except as specified herein:

- Webs with no longitudinal or vertical post-tensioning tendons—8.0 in.
- Webs with only longitudinal (or vertical) post-tensioning tendons—12.0 in.
- Webs with both longitudinal and vertical tendons—15.0 in.

The minimum thickness of ribbed webs may be taken as 7.0 in.

5.12.5.3.11c—Overall Cross-Section Dimensions

Overall dimensions of the box girder cross-section should preferably not be less than that required to limit live load plus impact deflection calculated using the gross section moment of inertia and the secant modulus of elasticity to $1/1,000$ of the span. The live loading shall consist of all traffic lanes fully loaded and adjusted for the number of loaded lanes as specified in Article 3.6.1.1.2. The live loading shall be considered to be uniformly distributed to all longitudinal flexural members.

C5.12.5.3.11c

With four lanes of live load and using applicable reduction factors, the live load deflection of the model of the Corpus Christi Bridge was approximately $L/3,200$ in the main span. The deflection limit of $L/1,000$ was arbitrarily chosen to provide guidance concerning the maximum live load deflections anticipated for segmental concrete bridges with normal dimensions of the box girder cross-section.

Girder depth and web spacing determined in accordance with the following dimensional ranges will generally provide satisfactory deflection behavior:

- Constant depth girder

$$1/5 > d_o/L > 1/30$$

optimum $1/18$ to $1/20$

where:

d_o = girder depth (ft)

L = span length between supports (ft)

In case of incrementally launched girders, the girder depth should preferably be between the following limits:

$$\text{For } L = 100 \text{ ft, } 1/15 < d_o/L < 1/12$$

$$\text{For } L = 200 \text{ ft, } 1/13.5 < d_o/L < 1/11.5$$

$$\text{For } L = 300 \text{ ft, } 1/12 < d_o/L < 1/11$$

- Variable depth girder with straight haunches at pier $^{1/16} > d_o/L > ^{1/20}$ optimum $^{1/18}$
at center of span $^{1/22} > d_o/L > ^{1/28}$ optimum $^{1/24}$
A diaphragm will be required at the point where the bottom flange changes direction.
- Variable depth girder with circular or parabolic haunches at pier $^{1/16} > d_o/L > ^{1/20}$
optimum $^{1/18}$
at center of span $^{1/30} > d_o/L > ^{1/50}$
Depth width ratio
A single cell box should preferably be used when $d_o/b \geq ^{1/6}$
A two cell box should preferably be used when $d_o/b < ^{1/6}$
where:
 b = width of the top flange

If in a single cell box the limit of depth to width ratio given above is exceeded, a more rigorous analysis is required and longitudinal edge beams at the tip of the cantilever may be required to distribute loads acting on the cantilevers. An analysis for shear lag should be made in such cases. Transverse load distribution is not substantially increased by the use of three or more cells.

5.12.5.3.12—Seismic Design

Segmental superstructure design with moment resisting column to superstructure connections shall consider the inelastic hinging forces from columns in accordance with Article 3.10.9.4.3. Bridge superstructures in Seismic Zones 3 and 4 with moment resisting column to superstructure connections shall be reinforced with ductile details to resist longitudinal and transverse flexural demands produced by column plastic hinging.

Segment joints shall provide capacity to transfer seismic demands.

Superstructure prestressing tendons shall be designed to remain below yield for the combined dead load plus seismic demands. The stress in the tendon may be computed by detailed moment curvature analysis, with the stress in tendon computed by strain compatibility with the section and the stress in unbonded tendon computed using global displacement compatibility between bonded sections of tendons located within the span.

C5.12.5.3.12

The distinction between bonded tendons and unbonded tendons with respect to seismic behavior reflects the general condition that bonded tendons are effectively bonded at all sections along the span, whereas unbonded tendons are effectively bonded at only their anchorages and intermediate bonded sections, such as deviators. Hence, the overall section strength achieved with bonded tendons is typically larger than that achieved with unbonded tendons. However, both bonded and unbonded tendons have been shown to provide significant displacement ductility (Megally et al., 2003).

The *AASHTO Guide Specifications for LRFD Seismic Bridge Design* (2023) determine the resistance of concrete structures using nonlinear “push-over” analysis. Various peer review teams urged this methodology following the Loma Prieta and Northridge earthquakes, in order to better access global behavior, and to achieve more economically-justifiable designs. Superstructures are designed for forces to resist plastic-hinging of the column(s). Frames are modeled using soil springs on the substructure, and stress-strain relationships for the concrete and steel. The frame is pushed, to incur plastic hinges in the columns, and reaches a point of collapse. The resulting displacement must be greater

than that from a three-dimensional linear dynamic analysis. The acceleration response spectrum (ARS) may be generic for the soil type and anticipated acceleration, or be developed for the specific bridge site.

5.12.5.4—Types of Segmental Bridges

5.12.5.4.1—General

Bridges designed for segmentally placed superstructures shall conform to the requirements specified herein, based on the concrete placement method and the erection methods to be used.

C5.12.5.4.1

Precast segmental bridges are normally erected by balanced cantilever, use of erection trusses, or progressive placement.

Bridges erected by balanced cantilever or progressive placement normally utilize internal tendons. Bridges built with erection trusses may utilize internal tendons, external tendons, or combinations thereof. Due to considerations of segment weight, span lengths for precast segmental box girder bridges, except for cable-stayed bridges, generally do not exceed 400 ft.

5.12.5.4.2—Details for Precast Construction

The compressive strength of precast concrete segments shall not be less than 2.5 ksi prior to removal from the forms and shall have a maturity equivalent to 14 days at 70°F prior to assembly into the structure.

C5.12.5.4.2

This provision intends to limit the magnitude of construction deflections and to prevent erratic construction deflections and creep.

To aid in geometry control, the stress across the joint should be as uniform as practical until the epoxy has cured. Having a difference between maximum and minimum compressive stress of no more than 0.060 ksi is recommended.

Multiple small-amplitude shear keys at match-cast joints in webs of precast segmental bridges shall extend over as much of the web as is compatible with other details. Details of shear keys in webs should be similar to those shown in Figure 5.12.5.4.2-1. Alignment keys shall also be provided in top and bottom slabs. Keys in the top and bottom slabs may be larger single-element keys.

Small-amplitude shear keys in the webs are less susceptible to stress concentrations and construction damage, which will result in loss of geometry control, than larger single-element keys. Alignment keys in the top and bottom flanges are less susceptible to such damage.

Figure 5.12.5.4.2-1—Example of Fine Indentation Shear Keys

Joints in precast segmental bridges shall be either cast-in-place closures or match cast epoxied joints.

Where an epoxy joint is specified, a temporary or permanent prestressing system shall provide a minimum compressive stress of 0.030 ksi and an average stress of not less than 0.040 ksi across the joint until the epoxy has cured. If the segment or segments being erected are supported by the prestressing system, the stresses due to the prestressing and the weight of the segment being

Match casting is necessary to ensure control of the geometry upon reassembly of the segments.

Epoxy on both faces serves as a lubricant during placement of the segments, prevents water intrusion, provides a seal to prevent cross-over during grouting, and provides some tensile strength across the joint.

The use of dry joints (identified as Type B in past versions of these Specifications) was eliminated with the adoption of the 2003 revisions due to the critical nature of post-tensioning reinforcement and the need for a multiple layer protection system. Failures of some post-tensioning reinforcement in Florida and Europe due to corrosion have resulted in a review of the effectiveness of previous multiple layer protection systems. The most rigorous review was performed by the British Concrete Society and the recommendations are contained in the report titled "Durable Post-Tensioned Concrete Bridges." This European report codifies the need for a three-level protection system and suggested details to achieve the required results. Improved grout and duct materials and methods are also discussed. As a result of this European report and studies by Dr. John Breen of the University of Texas, Austin, the multiple-level protection system for post-tensioning has been universally accepted.

The *AASHTO LRFD Bridge Construction Specifications* require this temporary stress to ensure full bond and to prevent uneven epoxy thickness. Such variations could lead to a systematic accumulation of geometric error. Large stress changes on epoxy joints should be avoided during the initial curing period.

erected shall be combined and the same stress limits apply.

5.12.5.4.3—Details for Cast-in-Place Construction

Joints between cast-in-place segments shall be specified as either intentionally roughened to expose coarse aggregate or keyed.

The width of closure joints shall permit the coupling of the tendon ducts.

Diaphragms shall be provided at abutments, piers, hinge joints, and bottom flange angle points in structures with straight haunches. Diaphragms shall be substantially solid at piers and abutments, except for access openings and utility holes. Diaphragms shall be sufficiently wide as required by design.

5.12.5.4.4—Cantilever Construction

The provisions specified herein shall apply to both precast and cast-in-place cantilever construction.

Longitudinal tendons may be anchored in the webs, in the slab, or in blisters built out from the web or slab. A minimum of two longitudinal tendons shall be anchored in each segment.

The cantilevered portion of the structure shall be investigated for overturning during erection. The factor of safety against overturning shall not be less than 1.5 under any combination of loads, as specified in Article 5.12.5.3.3. Minimum wind velocity for erection stability analyses shall be 55 mph, unless a better estimate of probable wind velocity is obtained by analysis or meteorological records.

Continuity tendons shall be anchored at least one segment beyond the point where they are theoretically required for stresses.

The segment lengths assumed in the design shall be shown on the plans. Any changes proposed by the Contractor shall be supported by reanalysis of the construction and computation of the final stresses.

The formtraveler weight assumed in stress and camber calculations shall be stated on the plans.

C5.12.5.4.3

The *AASHTO LRFD Bridge Construction Specifications* require vertical joints to be keyed. However, proper attention to roughened joint preparation is expected to ensure bond between the segments, providing better shear strength than shear keys.

C5.12.5.4.4

Permanent or temporary longitudinal strand or bar tendons satisfy the requirement to anchor a minimum of two tendons in each segment.

Stability during erection may be provided by moment resisting column/superstructure connections, falsework bents, or a launching girder. Loads to be considered include construction equipment, forms, stored material, and wind.

The 70 mph three-second gust wind speed, when applied with a load factor of 1.0, is equivalent to the 100 mph fastest-mile wind speed applied with a load factor of 0.30 shown in Table 3.4.1-1 in earlier Specifications. The 100 mph fastest-mile wind speed applied with a load factor of 0.30 was meant to be equivalent to 55 mph fastest-mile wind speed applied with a load factor of 1.0.

Tendon force requires an “induction length” due to shear lag before it may be assumed to be effective over the whole section.

Lengths of segments for free cantilever construction typically range between 8.0 and 18.0 ft. Lengths vary with the construction method, the span length and location within the span.

Formtravelers for a typical 40.0-ft wide, two-lane bridge with 15.0- to 16.0-ft segments may be estimated to weigh 160 to 180 kips. Weight of formtravelers for wider two-cell box sections may range up to 280 kips. Segment length is adjusted for deeper and heavier segments to control segment weight. Consultation with contractors experienced in free cantilever construction is recommended to obtain a design value for formtraveler weight for a specific bridge cross-section.

5.12.5.4.5—Span-by-Span Construction

Provisions shall be made in design of span-by-span construction for accumulated construction stresses due to the change in the structural system as construction progresses.

Forces and stresses due to the changes in the structural system, in particular the effects of the application of a load to one system and its removal from a different system, shall be accounted for. Redistribution of such forces and stresses by creep shall be taken into account and allowance made for possible variations in the creep rate and magnitude.

5.12.5.4.6—Incrementally Launched Construction

5.12.5.4.6a—General

Stresses under all stages of launching shall not exceed the limits specified in Article 5.12.5.3.3.

Provision shall be made to resist the frictional forces on the substructure during launching and to restrain the superstructure if the structure is launched down a gradient.

5.12.5.4.6b—Force Effects Due to Construction Tolerances

Force effects due to permissible construction tolerances shall be considered, both during construction and for the in-service structure. Unless otherwise specified in the contract documents, the tolerances shall be taken as:

- In the longitudinal direction between two adjacent bearings.....0.2 in.
- In the transverse direction between two adjacent bearings.....0.1 in.
- Between the fabrication area and the launching equipment in the longitudinal and transverse direction0.1 in.
- Lateral deviation at the outside of the webs.....0.1 in.

The horizontal force acting on the lateral guides of the launching bearings shall be taken as less than one percent of the vertical support reaction.

For design of the in-service structure, locked-in force effects from construction tolerances, EL, shall be included in load combinations according to Table 3.4.1-1. For forces and stresses during construction, one half the effects of construction tolerances and one half the effects of temperature

C5.12.5.4.5

Span-by-span construction is defined as construction where the segments, either precast or cast-in-place, are assembled or cast on falsework supporting one entire span between permanent piers. The falsework is removed after application of post-tensioning to make the span capable of supporting its own weight and any construction loads. Additional stressing may be utilized after adjacent spans are in place to develop continuity over piers.

C5.12.5.4.6a

Incrementally launched girders are subject to reversal of moments during launching. Temporary piers, a launching nose, or both may be used to reduce launching stresses.

For determining the critical frictional forces, the friction on launching bearings should be assumed to vary between 0 and 4 percent, whichever is critical. The upper value may be reduced to 3.5 percent if pier deflections and launching jack forces are monitored during construction. These friction coefficients are only applicable to bearings employing a combination of virgin polytetrafluoroethylene (PTFE) and stainless steel with a roughness of less than 1.0×10^{-4} in.

C5.12.5.4.6b

The Designer can reduce tolerances through construction details, in which case the force effects may be reduced accordingly. Permanent bearings grouted in place after launching has been completed is an example of a construction detail to alleviate tolerance force effects.

gradient shall be added together and applied as load TG in Table 5.12.5.3.3-1. Concrete stresses due to the load combinations in Table 5.12.5.3.3-1 shall not exceed those specified in Article 5.12.5.3.3.

5.12.5.4.6c—Design Details

Piers and superstructure diaphragms at piers shall be designed to permit jacking of the superstructure during all launching stages and for the installation of permanent bearings. Frictional forces during launching shall be considered.

Local stresses that may develop at the underside of the web during launching shall be investigated. The following requirements shall be satisfied:

- Launching pads shall be placed not closer than 3.0 in. to the outside of the web,
- Concrete cover between the soffit and post-tensioning ducts shall not be less than 6.0 in., and
- Bearing pressures at the web/soffit corner shall be investigated and the effects of ungrouted ducts and any eccentricity between the intersection of the centerlines of the web and the bottom slab and the centerline of the bearing shall be considered.

C5.12.5.4.6c

The dimensional restrictions on placement of launching bearings are shown in Figure C5.12.5.4.6c-1. Eccentricity between the intersection of the centerlines of the web and the bottom slab and the centerline of the bearing is illustrated in Figure C5.12.5.4.6c-2.

Figure C5.12.5.4.6c-1—Location of Launching Pads

Figure C5.12.5.4.6c-2—Eccentric Reaction at Launching Pads

The straight tendons required for launching shall be sufficient to meet the service and strength limit state requirements of these Specifications. Not more than 50 percent of the tendons shall be coupled at one construction joint. Anchorages and locations for the

The stresses in each cross-section change from tension to compression during launching. These tensile stresses during launching are counteracted by the straight tendons. The straight tendons are stressed at an early concrete age (e.g., three days).

straight tendons shall be designed for the concrete strength at the time of tensioning.

The faces of construction joints shall be provided with keys or a roughened surface with a minimum roughness amplitude of 0.25 in. Bonded nonprestressed reinforcement shall be provided longitudinally and transversely at all exterior concrete surfaces of the girder. The longitudinal reinforcement shall run continuously through the segments and joints. Longitudinal reinforcement shall not be spliced at joints.

5.12.5.4.6d—Design of Construction Equipment

Where construction equipment for incremental launching is shown on the contract documents, the design of such equipment shall include, but not be limited to the following features:

- The construction tolerances in the sliding surface at the bottom of the launching nose shall be limited to those of the superstructure, as specified in Article 5.12.5.4.6b.
- The introduction of the support reactions in the launching nose shall be investigated with respect to strength, stability, and deformation.
- Launching bearings shall be designed in such a way that they can compensate for local deviations of the sliding surface of up to 0.08 in. by elastic deformation.
- The launching equipment shall be sized for friction in accordance with Article 5.12.5.4.6a and the actual superstructure gradient.
- The launching equipment shall be designed to ensure that a power failure will not lead to uncontrolled sliding of the superstructure.
- The friction coefficient between concrete and the hardened profiled steel surfaces of the launching equipment shall be taken as 60 percent at the service limit state and the friction shall exceed the driving forces by 30 percent.

The forms for the sliding surfaces underneath and outside the web shall be wear-resistant and sufficiently stiff so that their deflection during casting does not exceed 0.08 in.

5.12.5.5—Use of Alternative Construction Methods

When permitted by contract documents that do not require value engineering, the Contractor may be allowed to choose alternative construction methods and a modified post-tensioning layout suitable for the selected construction method. In such a case, the Contractor shall supply a structural analysis, documenting that the post-tensioning forces and eccentricities shown on the construction plans meet all

The inclined launching bearings, as opposed to horizontal permanent bearings, create forces at the launching jacks and at the pier tops.

Minimum reinforcement of the equivalent of #4 bars spaced at 5.0 in. both longitudinally and transversely on all exterior concrete surfaces of the girder, with the longitudinal bars running across the joints has been recommended in past editions of this specification. Splices of the longitudinal bars may be located just to one side of joints such that no length of the splice is running through the joints.

C5.12.5.5

Opinions vary among state bridge engineers and consultants about the desirability of permitting alternate construction methods. Some state transportation departments do not permit any deviation from the details and construction methods shown on the plans and specified in the contract special provisions. Other states permit great latitude for contractor submission of alternate construction methods. An

requirements of the design specifications. If additional post-tensioning is required for construction stages or other reasons, it shall be demonstrated that the stresses at critical sections in the final structure meet the allowable stress provisions of the design specifications. Removal of temporary post-tensioning to achieve such conditions shall be permissible. Use of additional nonprestressed reinforcement for construction stages shall be permitted. All extra materials required for construction stages shall be provided by the Contractor at no cost to the Owner.

Value engineering provisions may be included in the contract special provisions permitting alternative construction methods that require a complete redesign of the final structure. The Contractor's engineering expenses for preparing the value engineering design and the Owner's engineering expenses for checking the design shall be considered as part of the cost of the redesign structure.

of the final structure. The Contractor's engineering expenses for preparing the value engineering design and the Owner's engineering expenses for checking the design shall be considered as part of the cost of the redesign structure.

Pier spacing, alignment, outside concrete, appearance, and dimensions shall not be changed under value engineering proposals, except when contract documents define such changes as being permitted.

For the value engineering, the Contractor shall provide a complete set of design computations and revised contract documents. The value engineering redesign shall be prepared by a Professional Civil Engineer or Structural Engineer experienced in segmental bridge design. Upon acceptance of a value engineering redesign, the Professional Civil Engineer, or Structural Engineer responsible for the redesign shall become the Engineer in Responsible Charge. Based upon the jurisdiction in which the project resides, the Owner shall specify whether a Professional Civil Engineer or Structural Engineer is required for the redesign.

example of the latter is presented below, which is taken verbatim from the contract documents for a California bridge project:

“Alternative Proposals—Continuous cast-in-place prestressed box girder bridges have been designed to be fully supported during construction. Except as provided herein, such bridges shall be constructed on falsework and in accordance with the provisions in Section 51, ‘Concrete Structures,’ of the Standard Specifications.

“The Contractor may submit proposals for such bridges which modify the original design assumptions for dead load support or the requirements in Section 51, ‘Concrete Structures,’ of the Standard Specifications. Such proposals are subject to the following requirements and limitation.

“The structure shall, after completion, have a capacity to carry or resist loads at least equal to those used in the design of the bridge shown on the plans. When necessary, strengthening of the superstructure and the substructure will be required to provide such capacity and to support construction loads at each stage of construction.

“It is recommended that the Engineer in Responsible Charge for the value engineering redesign be licensed and that the working drawings and calculations are signed and sealed accordingly.

“All proposed modifications shall be designed in accordance with the bridge design specifications currently employed by the Department.

“Modifications may be proposed in the thickness of girders and deck slabs, the thickness and length of overhang, the structure depth, the number of girders, and the amount and location of reinforcing steel or prestressing force. The strength of the concrete used may be increased, but the strength employed for design or analysis shall not exceed 6,000 psi.

“Modifications may also be proposed in the requirements in ‘Prestressing Concrete’ of these special provisions which pertain to the minimum amount of prestressing force which must be provided by full length draped tendons.

“No modifications will be permitted in the width of the bridge. Fixed connections at the tops and bottoms of columns shown on the plans shall not be eliminated.

“Temporary prestressing tendons, if used, shall be detensioned and any temporary ducts shall be filled with grout before completion of the work. Temporary tendons shall be either removed or fully encased in grout before completion of the work.

“The Contractor shall be responsible for determining construction camber and obtaining the final profile grade as shown on the plans. The Contractor shall provide the Engineer with diagrams showing the predicted deck profile at each construction stage for all

portions of the completed bridge. Any remedial measures necessary to correct deviation from the predicted camber will be the responsibility of the Contractor.

“The Contractor shall furnish to the Engineer complete working drawings and checked calculations for all changes proposed, including revisions in camber and falsework requirements, in accordance with the provisions of Section 5-1.02 of the AASHTO Standard Specifications. The calculations must verify that all requirements are satisfied. Such drawings and calculations shall be signed by an Engineer who is registered as a Civil Engineer in the State of California.

“Working drawings and calculations shall be submitted sufficiently in advance of the start of the affected work to allow time for review by the Engineer and correction by the Contractor of the drawings without delaying the work. Such time shall be proportional to the complexity of the work, but in no case shall such time be less than eight weeks.

“The Contractor shall reimburse the State for the cost of investigating the proposal. The Department may deduct such amount from any monies due, or that may become due, the Contractor under contract.

“The Engineer shall be the sole judge as to the acceptability of any proposal and may disapprove any proposal which in his judgment may not produce a structure which is at least equivalent in all respects to the planned structure.

“Any additional materials required or increased costs resulting from the use of such proposal will be considered to be for the convenience of the Contractor and no additional payment will be made therefore.”

5.12.5.6—Segmentally Constructed Bridge Substructures

5.12.5.6.1—General

Pier and abutment design shall conform to Section 11 and to the provisions of this section. Consideration shall be given to erection loads, moments, and shears imposed on piers and abutments by the construction method shown in the contract documents. Auxiliary supports and bracing shall be shown as required. Hollow, rectangular precast segmental piers shall be designed in accordance with Article 5.6.4.7. The area of discontinuous longitudinal nonprestressed reinforcement may be as specified in Article 5.12.5.6.3.

5.12.5.6.2—Construction Load Combinations

Tensile stresses in vertically prestressed substructures during construction shall be computed for applicable load combinations of Table 5.12.5.3.3-1.

C5.12.5.6.1

Nonsegmentally constructed substructures are addressed in Sections 10 and 11 and in Article 5.12.5.3.4b.

5.12.5.6.3—Longitudinal Reinforcement of Hollow, Rectangular Precast Segmental Piers

The minimum area of discontinuous longitudinal nonprestressed reinforcement in hollow, rectangular precast segmental piers shall satisfy the shrinkage and temperature reinforcement provisions specified in Article 5.10.6.

C5.12.5.6.3

Minimum longitudinal reinforcement of hollow, rectangular precast segmental piers is based on Article 5.10.6 for shrinkage and temperature reinforcement. This provision reflects the satisfactory performance of several segmental piers constructed between 1982 and 1995, with longitudinal reinforcement ratios ranging from 0.0014 to 0.0028. The discontinuous longitudinal bars in precast segmental piers do not carry significant loads. Tensile reinforcement of precast segmental piers is provided by post-tensioning tendons.

5.12.6—Arches

5.12.6.1—General

The shape of an arch shall be selected with the objective of minimizing flexure under the effect of combined permanent and transient loads.

5.12.6.2—Arch Ribs

The in-plane stability of the arch rib(s) shall be investigated using a modulus of elasticity and moment of inertia appropriate for the combination of loads and moment in the rib(s).

In lieu of a rigorous analysis, the effective length for buckling may be estimated as the product of the arch half span length and the factor specified in Table 4.5.3.2.2c-1.

For the analysis of arch ribs, the provisions of Article 4.5.3.2.2 may be applied. When using the approximate second-order correction for moment specified in Article 4.5.3.2.2c, an estimate of the short-term secant modulus of elasticity may be calculated, as specified in Article 5.4.2.4, based on a strength of $0.40f'_c$.

Arch ribs shall be reinforced as compression members. The minimum reinforcement of one percent of the gross concrete area shall be evenly distributed about the section of the rib. Confinement reinforcement shall be provided as required for columns.

Unfilled spandrel walls greater than 25.0 ft in height shall be braced by counterforts or diaphragms.

Spandrel walls shall be provided with expansion joints. Temperature reinforcement shall be provided corresponding to the joint spacing.

The spandrel wall shall be jointed at the springline.

The spandrel fill shall be provided with effective drainage. Filters shall be provided to prevent clogging of drains with fine material.

C5.12.6.2

Stability under long-term loads with a reduced modulus of elasticity may govern the stability. In this condition, there would typically be little flexural moment in the rib, the appropriate modulus of elasticity would be the long-term tangent modulus, and the appropriate moment of inertia would be the transformed section inertia. Under transient load conditions, the appropriate modulus of elasticity would be the short-term tangent modulus, and the appropriate moment of inertia would be the cracked section inertia, including the effects of the factored axial load.

The value indicated may be used in stability calculations because the scatter in predicted versus actual modulus of elasticity is greater than the difference between the tangent modulus and the secant modulus at stress ranges normally encountered.

The long-term modulus may be found by dividing the short-term modulus by the creep coefficient.

Under certain conditions the moment of inertia may be taken as the sum of the moment of inertia of the deck and the arch ribs at the quarter point. A large deflection analysis may be used to predict the in-plane buckling load. A preliminary estimate of second-order moments may be made by adding to the first-order moments the product of the thrust and the vertical deflection of the arch rib at the point under consideration.

ACI 207.2R (2007) contains a discussion of joint spacing and temperature reinforcement of restrained walls.

Drainage of the spandrel fill is important to ensure durability of the concrete in the rib and the spandrel walls and to control the unit weight of the spandrel fill. Drainage details should keep the drainage water from running down the ribs.

5.12.7—Culverts

5.12.7.1—General

The soil structure aspects of culvert design are specified in Section 12.

5.12.7.2—Design for Flexure

The provisions of Article 5.6 shall apply.

5.12.7.3—Design for Shear in Slabs of Box Culverts

The provisions of Article 5.7 apply unless modified herein. For slabs of box culverts under 2.0 ft or more fill, nominal shear resistance V_c may be determined as the lesser of the following:

$$V_c = \left(0.0676 \lambda \sqrt{f'_c} + 4.6 \frac{A_s}{bd_e} \frac{V_u d_e}{M_u} \right) bd_e \quad (5.12.7.3-1)$$

$$V_c \leq 0.126 \lambda \sqrt{f'_c} bd_e \quad (5.12.7.3-2)$$

where:

- λ = concrete density modification factor, as specified in Article 5.4.2.8
- A_s = area of reinforcement in the design width (in.²)
- b = design width (in.)
- d_e = effective depth from extreme compression fiber to the centroid of the tensile force in the tensile reinforcement (in.)
- V_u = shear from factored loads (kip)
- M_u = factored moment at the section (kip-in.)

For single-cell box culverts only, V_c for slabs monolithic with walls need not be taken to be less than $0.0948 \lambda \sqrt{f'_c} bd_e$, and V_c for slabs simply supported need not be taken to be less than $0.0791 \lambda \sqrt{f'_c} bd$. The quantity $V_u d_e / M_u$ shall not be taken to be greater than 1.0 where M_u is the factored moment occurring simultaneously with V_u at the section considered. The provisions of Articles 5.7 and 5.12.8.6 shall apply to slabs of box culverts under less than 2.0 ft of fill and to sidewalls.

5.12.8—Footings

5.12.8.1—General

Provisions herein shall apply to the design of isolated footings, combined footings, and foundation mats.

In sloped or stepped footings, the angle of slope or depth and location of steps shall be such that design requirements are satisfied at every section.

C5.12.7.3

Eq. 5.12.7.3-1, as originally proposed, included an additional multiplier to account for axial compression. Because the effect was considered relatively small, it was deleted from Eq. 5.12.7.3-1. However, if the Designer wishes, effect of axial compression may be included by multiplying the results of Eq. 5.12.7.3-1 by the quantity $(1 + 0.04 N_u / V_u)$.

The lower limits of $0.0948 \lambda \sqrt{f'_c}$ and $0.0791 \lambda \sqrt{f'_c}$ are compared with test results in Figure C5.12.7.3-1 with $\lambda = 1.0$.

Figure C5.12.7.3-1—Culvert Test Results

C5.12.8.1

Although the provisions of Article 5.12.8 apply to isolated footings supporting a single column or wall, most of the provisions are generally applicable to combined footings and mats supporting several columns or walls or a combination thereof.

Circular or regular polygon-shaped concrete columns or piers may be treated as square members with the same area for the location of critical sections for moment, shear, and development of reinforcement in footings.

5.12.8.2—Loads and Reactions

The resistance of foundation material for piles shall be as specified in Section 10.

Where an isolated footing supports a column, pier, or wall, the footing shall be assumed to act as a cantilever. Where a footing supports more than one column, pier, or wall, the footing shall be designed for the actual conditions of continuity and restraint.

For the design of footings, unless the use of special equipment is specified to ensure precision driving of piles, it shall be assumed that individual driven piles may be out of planned position in a footing by either 6.0 in. or one quarter of the pile diameter and that the center of a group of piles may be 3.0 in. from its planned position. For pile bents, the contract documents may require a 2.0 in. tolerance for pile position, in which case that value should be accounted for in the design.

5.12.8.3—Resistance Factors

For determination of geotechnical requirements for footing size and number of piles, the resistance factors, ϕ , for soil-bearing pressure and for pile resistance as a function of the soil shall be as specified in Section 10. Resistance factors for structural design shall be as specified herein.

5.12.8.4—Moment in Footings

The critical section for flexure shall be taken at the face of the column, pier, or wall. In the case of columns that are not rectangular, the critical section shall be taken at the side of the concentric rectangle of equivalent area. For footings under masonry walls, the critical section shall be taken as halfway between the center and edge of the wall. For footings under metallic column bases, the critical section shall be taken as halfway between the column face and the edge of the metallic base.

5.12.8.5—Distribution of Moment Reinforcement

In one-way footings and two-way square footings, reinforcement shall be distributed uniformly across the entire width of the footing.

The following guidelines apply to the distribution of reinforcement in two-way rectangular footings:

C5.12.8.2

The assumption that the as-built location of piles may differ from the planned location recognizes the construction variations sometimes encountered and is consistent with the tolerances allowed by the *AASHTO LRFD Bridge Construction Specifications*. Lesser variations may be assumed if the contract documents require the use of special equipment, such as templates, for more precise driving.

For noncircular piles, the larger cross-sectional dimension should be used as the “diameter.”

C5.12.8.4

Moment at any section of a footing may be determined by passing a vertical plane through the footing and computing the moment of the forces acting on one side of that vertical plane.

- In the long direction, reinforcement shall be distributed uniformly across the entire width of footing.
- In the short direction, a portion of the total reinforcement, as specified by Eq. 5.12.8.5-1, shall be distributed uniformly over a band width equal to the length of the short side of footing and centered on the centerline of column or pier. The remainder of reinforcement required in the short direction shall be distributed uniformly outside of the center band width of footing. The area of steel in the band width shall satisfy Eq. 5.12.8.5-1.

$$A_{s-BW} = A_{s-SD} \left(\frac{2}{\beta + 1} \right) \quad (5.12.8.5-1)$$

where:

A_{s-BW} = area of steel in the band width (in.²)
 A_{s-SD} = total area of steel in short direction (in.²)
 β = ratio of the long side to the short side of footing

5.12.8.6—Shear in Slabs and Footings

5.12.8.6.1—Critical Sections for Shear

In determining the shear resistance of slabs and footings in the vicinity of concentrated loads or reaction forces, the more critical of the following conditions shall govern:

- One-way action, with a critical section extending in a plane across the entire width and located at a distance taken as specified in Article 5.7.3.2.
- Two-way action, with a critical section perpendicular to the plane of the slab and located so that its perimeter, b_o , is a minimum but not closer than $0.5d_v$ to the perimeter of the concentrated load or reaction area.
- Where the slab thickness is not constant, critical sections located at a distance not closer than $0.5d_v$ from the face of any change in the slab thickness and located such that the perimeter, b_o , is a minimum.

C5.12.8.6.1

In the general case of a cantilever retaining wall, where the downward load on the heel is larger than the upward reaction of the soil under the heel, the critical section for shear is taken at the back face of the stem, as illustrated in Figure C5.12.8.6.1-1, in which d_v is the effective depth for shear.

Figure C5.12.8.6.1-1—Example of Critical Section for Shear in Footings

If a haunch has a rise-to-span ratio of 1:1 or more where the rise is in the direction of the shear force under investigation, it may be considered an abrupt change in section, and the design section may be taken as d_v into

Where a portion of a pile lies inside the critical section, the pile load shall be considered to be uniformly distributed across the width or diameter of the pile, and the portion of the load outside the critical section shall be included in the calculation of shear on the critical section.

5.12.8.6.2—One-Way Action

For one-way action, the shear resistance of the footing or slab shall satisfy the requirements specified in Article 5.7.3, except for culverts with 2.0 ft or more of fill, for which the provisions of Article 5.12.7.3 shall apply.

5.12.8.6.3—Two-Way Action

For two-way action for sections without transverse reinforcement, the nominal shear resistance, V_n in kips, of the concrete shall be taken as:

$$V_n = \left(0.063 + \frac{0.126}{\beta_c} \right) \lambda \sqrt{f'_c} b_o d_v \leq 0.126 \lambda \sqrt{f'_c} b_o d_v \quad (5.12.8.6.3-1)$$

where:

- β_c = ratio of long side to short side of the rectangle through which the concentrated load or reaction force is transmitted
- λ = concrete density modification factor, as specified in Article 5.4.2.8
- b_o = the perimeter of the critical section for shear (in.)
- d_v = effective shear depth (in.)

Where $V_u > \phi V_n$, shear reinforcement shall be added in compliance with Article 5.7.3.3, with angle θ taken as 45 degrees.

For two-way action for sections with transverse reinforcement, the nominal shear resistance, in kips, shall be taken as:

$$V_n = V_c + V_s \leq 0.192 \lambda \sqrt{f'_c} b_o d_v \quad (5.12.8.6.3-2)$$

in which:

$$V_c = 0.0632 \lambda \sqrt{f'_c} b_o d_v, \text{ and} \quad (5.12.8.6.3-3)$$

$$V_s = \frac{A_v f_y d_v}{s} \quad (5.12.8.6.3-4)$$

the span with d_v taken as the effective depth for shear past the haunch.

If a large-diameter pile is subjected to significant flexural moments, the load on the critical section may be adjusted by considering the pile reaction on the footing to be idealized as the stress distribution resulting from the axial load and moment.

C5.12.8.6.3

If shear perimeters for individual loads overlap or project beyond the edge of the member, the critical perimeter b_o should be taken as that portion of the smallest envelope of individual shear perimeter that will actually resist the critical shear for the group under consideration. One such situation is illustrated in Figure C5.12.8.6.3-1.

Figure C5.12.8.6.3-1—Modified Critical Section for Shear with Overlapping Critical Perimeters

5.12.8.7—Development of Reinforcement

For the development of reinforcement in slabs and footings, the provisions of Article 5.10.8 shall apply.

Critical sections for development of reinforcement shall be assumed to be at the locations specified in Article 5.12.8.4 and at all other vertical planes where changes of section or reinforcement occur.

5.12.8.8—Transfer of Force at Base of Column

All forces and moments applied at the base of a column or pier shall be transferred to the top of footing by bearing on concrete and by reinforcement. Bearing on concrete at the contact surface between the supporting and supported member shall not exceed the concrete-bearing strength, as specified in Article 5.6.5, for either surface.

Lateral forces shall be transferred from the pier to the footing in accordance with shear-transfer provisions specified in Article 5.7.4 on the basis of the appropriate bulleted item in Article 5.7.4.4.

Reinforcement shall be provided across the interface between supporting and supported member, either by extending the main longitudinal column or wall reinforcement into footings or by using dowels or anchor bolts.

Reinforcement across the interface shall satisfy the following requirements:

- All force effects that exceed the concrete bearing strength in the supporting or supported member shall be transferred by reinforcement;
- If load combinations result in uplift, the total tensile force shall be resisted by the reinforcement; and
- The area of reinforcement shall not be less than 0.5 percent of the gross area of the supported member, and the number of bars shall not be less than four.

The diameter of dowels, if used, shall not exceed the diameter of longitudinal reinforcement by more than 0.15 in.

At footings, the #14 and #18 main column longitudinal reinforcement that is in compression only may be lap spliced with footing dowels to provide the required area. Dowels shall be no larger than #11 and shall extend into the column a distance not less than either the development length of the #14 or #18 bars or the splice length of the dowels and into the footing a distance not less than the development length of the dowels.

5.12.9—Concrete Piles**5.12.9.1—General**

All loads resisted by the footing and the weight of the footing itself shall be assumed to be transmitted to the piles. Piles installed by driving shall be designed to

C5.12.9.1

The material directly under a pile-supported footing is not assumed to carry any of the applied loads.

resist driving and handling forces. For transportation and erection, a precast pile should be designed for not less than 1.5 times its self-weight.

Any portion of a pile where lateral support adequate to prevent buckling may not exist at all times shall be designed as a column.

The points or zones of fixity for resistance to lateral loads and moments shall be determined by an analysis of the soil properties, as specified in Article 10.7.3.13.4.

Concrete piles shall be embedded into footings or pile caps, as specified in Article 10.7.1.1. Anchorage reinforcement shall consist of either an extension of the pile reinforcement or the use of dowels. Uplift forces or stresses induced by flexure shall be resisted by the reinforcement. The steel ratio for anchorage reinforcement shall not be less than 0.005, and the number of bars shall not be less than four. The reinforcement shall be developed sufficiently to resist a force of $1.25f_yA_s$.

In addition to the requirements specified in Articles 5.12.9.1 through 5.12.9.5, piles used in the seismic zones shall conform to the requirements specified in Articles 5.11.3.2 or 5.11.4.5, whichever is applicable.

5.12.9.2—Splices

Splices in concrete of piles shall develop the axial, flexural, shear, and torsional resistance of the pile. Details of splices shall be shown in the contract documents.

5.12.9.3—Precast Reinforced Piles

5.12.9.3.1—Pile Dimensions

Precast concrete piles may be of uniform section or tapered. Tapered piling shall not be used for trestle construction, except for that portion of the pile that lies below the ground line, or in any location where the piles are to act as columns.

Where concrete piles are not exposed to salt water, they shall have a cross-sectional area measured above the taper of not less than 140 in.² Concrete piles used in salt water shall have a cross-sectional area of not less than 220 in.² The corners of a rectangular section shall be chamfered.

The diameter of tapered piles measured 2.0 ft from the point shall be not less than 8.0 in. where, for all pile cross-sections, the diameter shall be considered as the least dimension through the center of cross-section.

5.12.9.3.2—Reinforcement

Longitudinal reinforcement shall consist of not less than four bars spaced uniformly around the perimeter of the pile. The area of reinforcement shall not be less than

Locations where such lateral support does not exist include any portion of a pile above the anticipated level of scour or future excavation as well as portions that extend above ground, as in pile bents.

C5.12.9.2

The *AASHTO LRFD Bridge Construction Specifications* have provisions for short extensions or “buildups” for the tops of concrete piles. This allows for field corrections due to unanticipated events, such as breakage of heads or driving slightly past the cutoff elevation.

C5.12.9.3.1

A 1.0-in. connection chamfer is desirable, but smaller chamfers have been used successfully. Local experience should be considered.

1.5 percent of the gross concrete cross-sectional area measured above the taper.

The full length of longitudinal steel shall be enclosed with spiral reinforcement or equivalent hoops. The spiral reinforcement shall be as specified in Article 5.12.9.4.3.

5.12.9.4—Precast Prestressed Piles

5.12.9.4.1—Pile Dimensions

Prestressed concrete piles may be octagonal, square, or circular and shall conform to the minimum dimensions specified in Article 5.12.9.3.1.

Prestressed concrete piles may be solid or hollow. For hollow piles, precautionary measures, such as venting, shall be taken to prevent breakage due to internal water pressure during driving, ice pressure in trestle piles, or gas pressure due to decomposition of material used to form the void.

The wall thickness of cylinder piles shall not be less than 5.0 in.

5.12.9.4.2—Concrete Quality

The compressive strength of the pile at the time of driving shall not be less than 5.0 ksi. Air-entrained concrete shall be used in piles that are subject to freezing and thawing or wetting and drying.

5.12.9.4.3—Reinforcement

Unless otherwise specified by the Owner, the prestressing strands should be spaced and stressed to provide a uniform compressive stress on the cross-section of the pile of not less than 0.7 ksi at the service limit state.

The full length of the prestressing strands shall be enclosed with spiral reinforcement as follows:

For piles not greater than 24.0 in. in diameter:

- spiral wire not less than W3.9;
- spiral reinforcement at the ends of piles having a pitch of 3.0 in. for approximately 16 turns;
- the top 6.0 in. of pile having five turns of additional spiral winding at 1.0-in. pitch; and
- for the remainder of the pile, the strands enclosed with spiral reinforcement with not more than 6.0-in. pitch.

For piles greater than 24.0 in. in diameter:

- spiral wire not less than W4.0;
- spiral reinforcement at the end of the piles having a pitch of 2.0 in. for approximately 16 turns;
- the top 6.0 in. having four additional turns of spiral winding at 1.5-in. pitch; and
- for the remainder of the pile, the strands enclosed with spiral reinforcement with not more than 4.0-in. pitch.

C5.12.9.4.3

The purpose of the 0.7 ksi compression is to prevent cracking during handling and installation. A lower compression may be used if approved by the Owner.

For noncircular piles, use the least dimension through the cross-section in place of the “diameter.”

5.12.9.5—Cast-in-Place Piles

Piles cast in drilled holes may be used only where soil conditions permit.

Shells for cast-in-place piles shall be of sufficient thickness and strength to hold their form and to show no harmful distortion during driving or after adjacent shells have been driven and the driving core, if any, has been withdrawn. The contract documents shall stipulate that alternative designs of the shell be approved by the Engineer before any driving is done.

5.12.9.5.1—Pile Dimensions

Cast-in-place concrete piles may have a uniform section or may be tapered over any portion if cast in shells or may be bell-bottomed if cast in drilled holes or shafts.

The area at the butt of the pile shall be at least 100 in.² The cross-sectional area at the tip of the pile shall be at least 50.0 in.². For pile extensions above the butt, the minimum size shall be as specified for precast piles in Article 5.12.9.3.

5.12.9.5.2—Reinforcement

The area of longitudinal reinforcement shall not be less than 0.8 percent of A_g , with spiral reinforcement not less than W3.9 at a pitch of 6.0 in. The reinforcement shall be extended 10.0 ft below the plane where the soil provides adequate lateral restraint.

Shells that are more than 0.12 in. in thickness may be considered as part of the reinforcement. In corrosive environments, a minimum of 0.06 in. shall be deducted from the shell thickness in determining resistance.

Except where more restrictive requirements are specified in Article 5.11.3.2 for bridges in Seismic Zone 2 or Article 5.11.4.5 for bridges in Seismic Zones 3 or 4, the clear distance between parallel longitudinal, and parallel transverse reinforcing bars in cast-in-place concrete piling, shall not be less than the greater of the following:

- Five times the maximum aggregate size;
- 5.0 in.

5.13—ANCHORS**5.13.1—General**

Anchors complying with the provisions of this Article shall be designed, detailed and installed using the

C5.12.9.5

Cast-in-place concrete piles include piles cast in driven steel shells that remain in place and piles cast in unlined drilled holes or shafts.

The construction of piles in drilled holes should generally be avoided in sloughing soils, where large cobbles exist or where uncontrollable groundwater is expected. The special construction methods required under these conditions increase both the cost and the probability of defects in the piles.

The thickness of shells should be shown in the contract documents as “minimum.” This minimum thickness should be that needed for pile reinforcement or for strength required for usual driving conditions: e.g., 0.134 in. minimum for 14.0-in. pile shells driven without a mandrel. The *AASHTO LRFD Bridge Construction Specifications* require the Contractor to furnish shells of greater thickness, if necessary, to permit his choice of driving equipment.

C5.12.9.5.2

If the shell is circular and considered as reinforcing, the provisions of Articles 6.9.6, 6.12.2.3 and 6.12.3.2.2 can be utilized to determine capacities.

C5.13.1

ACI 318 uses pound units instead of the kip units used in these Specifications.

provisions of ACI 318, Chapter 17 which is incorporated by reference, unless those provisions are specifically amended herein. Note that all references to ACI 318-19, ACI 355.2-19, and ACI 355.4-19 are indicated as ACI 318, ACI 355.2, and ACI 355.4, respectively unless otherwise indicated.

The following types of cast-in-place and post-installed anchors as described in ACI 318, Article 17.1.2 may be used:

- Headed studs and headed bolts having a geometry that has been demonstrated to result in a pullout strength in uncracked concrete equal to or exceeding $1.4N_p$, where N_p is given in ACI 318, Eq. 17.6.3.2.2a;
- Hooked bolts having a geometry that has been demonstrated to result in a pullout strength without the benefit of friction in uncracked concrete equal to or exceeding $1.4N_p$, where N_p is given in ACI 318, Eq. 17.6.3.2.2b;
- Post-installed expansion (torque-controlled and displacement-controlled) anchors that meet the assessment criteria of ACI 355.2;
- Post-installed undercut anchors that meet the assessment criteria of ACI 355.2;
- Post-installed adhesive anchors meeting the assessment criteria of ACI 355.4;
- Post-installed screw anchors meeting the assessment criteria of ACI 355.2; and
- Attachment with shear lugs.

These Specifications shall not be used for the design of grouted anchors.

See ACI 17.3.1 for applicable concrete strengths for cast-in-place and post-installed anchors.

All design, material, testing, anchor, geometry and depth limitations, anchor spacing, and edge distances specified in ACI 318, Chapter 17 and acceptance requirements specified in ACI 318, Chapter 26 shall be satisfied for anchors designed or supplied under these provisions. Group effects, eccentricity of loading, presence or lack of anchor reinforcement, and the possibility of concrete cracking or splitting shall be considered in the design.

Lightweight concrete factors for anchor design shall comply with ACI 318, Chapter 17.

Post-installed mechanical anchors shall not be removed and reset.

Safety levels associated with ACI 318, Chapter 17 are intended only for in-service conditions rather than short-term handling and construction condition, or for impact or cyclic loads other than those associated with seismic events, and should not be used for those purposes except as noted herein.

Excerpts from ACI 318, Chapter 17 have been provided in this Article for emphasis. The absence herein of any provisions from the ACI 318, Chapter 17 does not negate their validity as part of that specification.

The various types of anchors covered by ACI 318, Chapter 17 are shown below.

Cast-in-place anchors: (a) hex head bolt with washer; (b) L-bolt; (c) J-bolt; and (d) welded headed stud

Post-installed anchors: (a) adhesive anchor; (b) undercut anchor; (c) Torque-controlled expansion anchors (c1) sleeve-type and (c2) stud type; (d) drop-in type displacement controlled expansion anchor; and (e) screw type anchors.

Shear Lug Plate Attachment Example

Figure C5.13.1-1—Anchor Types Included in ACI 318, Chapter 17 (Courtesy of ACI)

Further background and sample calculations for specific cases involving cast-in-place anchors and adhesive anchors can be found in PCA (2013) and Cook

For the purpose of these Specifications, anchors attaching pedestrian or bicycle rails or fences separated from the roadway by a traffic railing meeting the requirements of Section 13 need not be considered subject to the impact exclusion in ACI 318, Chapter 17.

The exclusion for impact loads need not apply to other attachments using post-installed anchors shown to have impact strength at least equal to their static strength as documented by testing or a combination of analysis and testing deemed appropriate by the Owner.

Design for seismic events shall comply with the appropriate provisions of ACI 318, Chapter 17.

Corrosion control shall be considered in any anchor application exposed to the elements.

5.13.2—General Strength Requirements

5.13.2.1—Failure Modes to be Considered

The following failure modes shall be considered as applicable:

- Tension
 - Tensile strength of anchor steel
 - Pullout—cast-in-place, post-installed expansion and undercut anchors
 - Concrete breakout—all types
 - Concrete splitting
 - Side-face blowout—headed anchors
 - Bond failure—adhesive anchors

et al. (2013), respectively, and for both types in ACI 355.3R. ACI 355.3R contains design examples for cast-in-place and post-installed anchors albeit with resistance factors that are not current with those specified ACI 318, Chapter 17.

The decision to not require the impact exclusion for the situation indicated is based on the references cited below. Additional references are available in the literature. The use of any documented increase in resistance due to impact behavior is not required but is an Owner option.

ACI 349-13 no longer requires the impact exclusion. Appendix F contains Dynamic Increase Factors (DIFs) for undercut and expansion anchors. Shirvani et al. (2004) has documentation of similar DIFs for expansion and undercut anchors in tension in both cracked and uncracked concrete.

The installation and inspection requirements specified in ACI 318-14, Article 17.8 were moved to Article 26.7 of ACI 318.

Dickey et al. documents the impact behavior of epoxy adhesive anchors and recommends DIFs. The amount of improved strength under impact loads is thought to be dependent on the adhesive used. Similar results were reported by Braimah et al. (2009).

Owners and Designers are responsible for understanding the advantages and disadvantages of a specific anchorage system prior to use. This information can be found in ACI 318 and individual manufacturer's literature.

Typical corrosion protection consists of the use of coatings or corrosion resistant materials. For adhesive anchors, the manufacturer's literature must document that the adhesive used is compatible with the type and extent of any coating used.

C5.13.2.1

The cited failure modes are illustrated schematically below.

anchors shall be determined by tests using the criteria of ACI 355.2 for mechanical anchors or ACI 355.4 for adhesive anchors. For adhesive anchors for which test data is not available at the time of design, the minimum characteristic bond stresses given in ACI 318, Table 17.6.5.2.5, with adjustments for sustained tensile loading and seismic situations may be used.

The factored resistance shall be determined by applying the resistance factors specified in Article 5.13.2.2 to the nominal resistance.

5.13.3—Seismic Design Requirements

The requirements of ACI 318 Article 17.10 shall apply to anchors used in the seismic load path on structures in Seismic Zones 2, 3, and 4 specified in Article 3.10.6.

Anchors intended to resist seismic forces shall be suitable for use in cracked concrete.

Material for anchor restraining reinforcement in Seismic Zones 2, 3, and 4 shall comply with the applicable provisions of Articles 5.4.3 and 5.11.

The provisions of ACI 318, Chapter 17 do not apply to the design of anchors in plastic hinge zones of concrete structures subject to earthquake forces. Anchors located in plastic hinge zones shall be designed to transfer loads directly to anchor reinforcement.

If the tensile component of the earthquake load (EQ) applied to a single anchor or anchor group does not exceed 20 percent of the Extreme Event I Limit State tensile load combination, it shall be permitted to design a single anchor or anchor group in accordance with ACI 318, Article 17.6 and the tensile strength requirements of ACI 318, Table 17.5.2.

If the shear component of the EQ applied to a single anchor or anchor group does not exceed 20 percent of the Extreme Event I Limit State shear load combination, it shall be permitted to design a single anchor or anchor

bound bond stresses permitted by ACI 355.4. The characteristic bond strength of a qualified adhesive in a specific situation may be much higher.

The resistance of post-installed anchors is sensitive to installation procedures. ACI 355.4 has special requirements for horizontal or upwardly inclined adhesive anchors.

C5.13.3

ACI 318, Chapter 17 uses the Seismic Design Categories (SDCs) A through F in ASCE/SEI 7 2010. ACI Chapter 17 requires seismic design for anchors used in structures in SDC C through F. SDC C applies to situations with moderate to intermediate seismic risk. SDC D and higher categories apply to high-risk situations.

A direct correlation between SDC and AASHTO Seismic Zones (SZs) is not straightforward. The basis of the design acceleration coefficients in the two documents are different, resulting in a lack of a one-to-one correlation between acceleration coefficient values.

Nevertheless, a comparison of the ASCE SDCs in Table 11.6-2 and the AASHTO seismic zones in Table 3.10.6-1 suggests that Seismic Zone 1 is a reasonable choice to represent SDCs A and B.

There is no distinction in the requirements in ACI 318, Chapter 17 for structures in SDC C, D, E, or F and therefore no distinction is made herein among Seismic Zones 2, 3, and 4.

ACI 355.2 and 355.4 have provisions for Simulated Seismic Tests for expansion and undercut anchors and for adhesive anchors, respectively.

ACI 318, Chapter 17 contains conceptual details for anchor restraining reinforcement.

The more extensive cracking and spalling expected in plastic hinge zones are behaviors beyond that anticipated by the concrete-governed resistance equations in ACI 318, Chapter 17. Where anchors must be located in regions of plastic hinging, they should be designed to transfer load directly to anchor reinforcement that is specifically designed to carry the anchor forces into the body of the member beyond the anchorage region. Configurations that rely on concrete tensile strength should not be used.

ACI 318, Articles 17.10.5.1 and 17.10.6.1 refer to the *strength-level earthquake-induced force*. The language here was added to supersede these articles and direct designers to the AASHTO LRFD Extreme Event I Limit State when considering these provisions.

group in accordance with ACI 318, Article 17.7 and the shear strength requirements of ACI 318, Table 17.5.2.

5.13.4—Installation

Unless Owner-supplied installation requirements are more stringent, the contract documents shall require compliance with the provisions of ACI 318, Article 26.7 as applicable to the type of anchor being installed.

5.14—DURABILITY

5.14.1—Design Concepts

Protective measures for durability shall satisfy the requirements specified in Article 2.5.2.1.

Concrete structures shall be designed to provide protection of the reinforcing and prestressing steel against corrosion throughout the life of the structure.

Special requirements that may be needed to provide durability shall be indicated in the contract documents. Portions of the structure shall be identified where any of the following are required:

- air-entrainment of the concrete;
- epoxy-coated or galvanized reinforcement;
- use of corrosion resistant bars complying with AASHTO M 334M/M 334;
- sealing or coating;
- special concrete additives;
- special curing procedures; and
- low permeability concrete,

or where the concrete is expected to be exposed to saltwater or to sulfate soils or water.

Decisions regarding the use of durability enhancing materials and strategies should be based on life cycle cost analysis. Factors to be considered may include, but are not limited to:

- associated savings from reduced cover, if any, versus potential problems;
- initial cost of durability enhancing materials and strategies versus long-term benefits;

C5.13.4

Anchor performance is dependent on proper installation which, as a minimum requires:

- qualified, and in some cases certified, installers and inspectors;
- compliance with written supplier instructions;
- adequate support of cast-in-place anchors prior to and during concrete placement;
- continuous monitoring of installation of adhesive anchors;
- compliance with the specified type, size, and procedures for hole drilling; and
- adequate cleaning and any other specified post-drilling hole preparation.

ACI 318, Article 26.7 contains special installation guidance for horizontal or upwardly inclined adhesive anchors.

C5.14.1

NCHRP (2013) points out that “durability” is not a single property of concrete but rather it is a series of properties required for the particular environment to which the concrete will be exposed during its service life. While material aspects of concrete design are a major factor in producing durable concrete structures, attention to design, detailing and construction QA/QC are also vital for a successful outcome.

The literature contains numerous reports and papers on concrete durability. This commentary contains information from several sources but should not be considered exhaustive, nor should it be interpreted as conflicting with documented good local experience with other durability enhancing policies or protocols.

Freyermuth (2009) lists the following options for achieving extended service life of concrete bridges, although the extension is not quantified:

- Use of high-performance concrete to decrease permeability.
- Use of prestressing to reduce or control cracking.
- Use of jointless bridges, or bridge segments, and integral bridges.
- Use of integral deck overlays on precast concrete segmental bridges in aggressive environments.
- Selective use of stainless steel reinforcing.

- negative impacts from any work over navigable waterways, major or congested roadways, environmentally sensitive areas, or active railroads;
- possible future issues when project requirements dictate a deck with less depth and/or cover than standard practice; and
- the impact of longer service life on user costs and worker safety.

Structures intended to provide extended service lives must have the following attributes:

- Conceived, sited, and designed to provide an acceptable level of reliability with respect to the natural environment and man-made loads.
- Properly constructed with suitable materials and details.
- Provided with adequate control of deck drainage, especially in areas where deicing salt is applied or environmental salt is present.
- Treated with timely preventative maintenance of protective coatings, drainage systems, joints, and bearings.

Design considerations for durability include concrete quality, z coatings, minimum cover, distribution and size of reinforcement, details, and crack widths or prestressing. Further guidance can be found in ACI Committee Report 222 (2001) and Poston et al. (1987).

The principal aim of these Specifications, with regard to durability is the prevention of corrosion of the reinforcing steel. There are provisions in the *AASHTO LRFD Bridge Construction Specifications* for air-entrainment of concrete and some special construction procedures for concrete exposed to sulfates or salt water. For unusual conditions, the contract documents should augment the provisions for durability.

The critical factors contributing to the durability of concrete structures are:

- adequate cover over reinforcement;
- nonreactive aggregate-cement combinations;
- thorough consolidation of concrete;
- adequate cementitious material;
- low W/CM ratio; and
- thorough curing, preferably with water.

5.14.2—Major Chemical and Mechanical Factors Affecting Durability

5.14.2.1—General

Design for durability should consider detrimental regional and site specific chemical and mechanical agents that can reduce durability.

C5.14.2.1

Table C5.14.2.1-1 summarizes defects which can reduce concrete durability, their manifestations, causes, time of appearance and some preventative actions, taken from NCHRP (2013) which cited Van Dam et al (1998). Additional information can be found in PCA (2011).

Table C5.14.2.1-1—Factors in Concrete Durability

Type of Materials-Related Defect	Surface Distress Manifestations and Locations	Cause or Mechanisms	Time of Appearance	Prevention or Reduction
Due to Physical Mechanisms				
Mechanical wear of decks and wearing surfaces decks and wearing surfaces	Abrasion and polishing, polishing, rutting	Tire contact, improper curing, water floating to surface	Varies	Proper curing, sealants
Freezing and thawing deterioration of hardened cement paste	Scaling or map cracking, generally initiating near joints or cracks; possible internal disruption of concrete matrix.	Deterioration of saturated cement paste due to repeated cycles of freezing and thawing.	1–5 years	Addition of air-entraining agent to establish protective air-void system.
Deicer scaling and deterioration	Scaling or crazing of the slab surface.	Deicing chemicals can amplify deterioration due to freezing and thawing and may interact chemically with cement hydration products.	1–5 years	Limiting W/C ratio to no more than 0.45, and providing a minimum 30-day drying period after curing before allowing the use of deicers.
Deterioration of aggregate due to freezing and thawing	Cracking parallel to joints and cracks and later spalling; maybe accompanied by surface staining.	Freezing and thawing of susceptible coarse aggregates results in fracturing or excessive dilation of aggregate.	10–15 years	Use of nonsusceptible aggregates or reduction in maximum coarse aggregate size.
Early age cracking	Map cracking	Shrinkage of concrete	<28 days	Shrinkage limits, fibers continuous wet cure
Due to Chemical Mechanisms				
Alkali-silica reaction (ASR)	Map cracking (rarely more than 2.0 in. deep) over entire slab area and accompanying pressure-related distresses (spalling, blowups).	Reaction between alkalis in cement and reactive silica in aggregate, resulting in an expansive gel and the degradation of the aggregate particle.	5–15 years	Use of nonsusceptible aggregates, addition of pozzolans, limiting of alkalis in concrete, addition of lithium salts.
Alkali-carbonate reaction	Map cracking over entire slab area and accompanying pressure-related distresses (spalling, blowups).	Expansive reaction between alkalis in cement and carbonates in certain Aggregates containing clay fractions.	5–15 years	Avoiding susceptible aggregates, or blending susceptible aggregate with nonreactive aggregate.
External sulfate attack	Fine cracking near joints and slab edges or map cracking over entire slab area.	Expansive formation of ettringite or gypsum that occurs when external sources of sulfate (e.g., groundwater, deicing chemicals) react with aluminates in cement or fly ash.	1–5 years	Minimizing tricalcium aluminate content in cement or using blended cements, Class F fly ash, or GGBFS.

(continued on next page)

Table C5.14.2.1-1 (continued)—Factors in Concrete Durability

Type of Materials-Related Defect	Surface Distress Manifestations and Locations	Cause or Mechanisms	Time of Appearance	Prevention or Reduction
Internal sulfate attack	Fine cracking near joints and slab edges or map cracking over entire slab area.	Formation of ettringite from internal sources of sulfate that results in either expansive disruption on the paste phase or fills available air voids.	1–5 years	Minimizing tricalcium aluminate content in cement, using low sulfate cement, eliminating source of slowly soluble sulfate, and use cements conforming to ASTM C150, C595, or C1157, and avoiding high curing temperatures.
Corrosion of embedded steel	Spalling, cracking, and deterioration at areas above or surrounding embedded steel.	Chloride ions penetrate concrete and corrode embedded steel.	3–10 years	Reducing the permeability of the concrete, providing adequate concrete cover, and coating steel.

5.14.2.2—Corrosion Resistance

Reinforcement that is susceptible to corrosion and is used in concrete exposed to deicing salts or salt water shall be protected by the use of low-permeability concrete and concrete cover to the reinforcement in accordance with Article 5.14.3 (or 5.10.1).

C5.14.2.2

Salt intrusion is slowed by drainage control, providing suitable cover, use of dense, low permeability concrete such as high performance concrete (HPC) and ultra-high performance concrete (UHPC), and control of cracking.

The effects of salt intrusion and depassivation due to carbonation can be mitigated by using corrosion inhibitors, coated reinforcing, bimetallic reinforcement, stainless steel reinforcing, or nonmetallic reinforcement such as fiber-reinforced polymer (FRP) composites. Without citing specifics of cost/benefit, it will generally be found that cost increases with each step in the reinforcing path above.

Prestressing contributes to control of salt intrusion by reducing in-service cracking. While some cracking may result from overloads, thermal gradients, and shrinkage, the cracks will generally close when the causative effect is reduced or eliminated. Beam ends exposed to salt-laden deck drainage have been found to be susceptible to corrosion damage resulting from water entering the beam via the strand ends. Tabatabai et al. (2004) document the benefit of coating the ends (end 2 feet in this study) with sealing materials and conclude that of four tested materials, a polymer resin coating was most effective and easiest to apply.

5.14.2.3—Freeze–Thaw Resistance

Air-entrained concrete, designated “AE” in Table 8.2.2-1 of the *AASHTO LRFD Bridge Construction Specifications*, shall be specified where the concrete will be subject to alternate freezing and

C5.14.2.3

Freeze–thaw cycles can lead to scaling of the concrete surface due to pressure caused by the expansion of water in the concrete. Use of air-entrainment, high-strength mixes, and low permeability are effective countermeasures,

thawing and exposure to deicing salts, saltwater, or other potentially damaging environments.

although air-entrainment can result in reduced strength and may not be compatible with HPC or high-strength concrete (HSC). Use of fly ash can be counterproductive if delayed strength gain exposes the concrete to freezing before sufficient strength has been developed. The use of air-entrainment is generally recommended when 20 or more cycles of freezing and thawing per year are expected at the location and exposure. Decks and rails are most vulnerable, whereas buried footings are seldom damaged by freeze-thaw action.

5.14.2.4—External Sulfate Attack

The provisions of *AASHTO LRFD Bridge Construction Specifications* Article 8.6.7 shall apply.

C5.14.2.4

Sulfate soils or water, sometimes called alkali, contain high levels of sulfates of sodium, potassium, calcium, or magnesia. Sulfate attack is a result of the growth of minerals caused by reaction of chemicals in the cement with sulfates that were in the mix, usually in the water but possibly in the aggregate. It debonds the aggregate, creates expansive pressure leading to crack or delamination. The causes and effects are similar to ASR. Use of Type II, Type V, or a blended cement are often indicated as well as use of approved material sources. Factors which reduce permeability are also usually helpful. Detwiler (2008) states that “Maximum limits on the water–cementitious materials ratio, combined with good concreting practices—especially good curing—are even more important to sulfate resistance than the right cement.” Salt water, water soluble sulfate in soil above 0.1 percent, or sulfates in water above 150 ppm justify use of the special construction procedures called for in *AASHTO LRFD Bridge Construction Specifications*. These include avoidance of construction joints between the levels of low water and the upper limit of wave action. For sulfate contents above 0.2 percent in soil or 1,500 ppm in water, special concrete mixes may be justified. Further guidance may be found in ACI 201 (2008), which provides recommended mix practices for various sulfate concentrations, or PCA (2011).

5.14.2.5—Delayed Ettringite Formation

Concrete temperatures during curing shall not exceed 160°F to minimize delayed ettringite formation.

5.14.2.6—Alkali–Silica Reactive Aggregates

The provisions of Article 8.3.4 of the *AASHTO LRFD Bridge Construction Specifications* shall apply.

C5.14.2.6

Aggregate reactivity issues such as ASR are usually handled by prescreening possible sources using laboratory tests to identify susceptibility. Most states have approved sources that largely eliminate aggregate reactivity. Use of low-alkali cement can also reduce susceptibility of a concrete mix.

5.14.2.7—Alkali–Carbonate Reactive Aggregates

Aggregates susceptible to alkali–carbonate reactivity shall not be used unless blended according to the appendix in ASTM C1105.

5.14.3—Concrete Cover

The provisions of Article 5.10.1 shall apply unless superseded by the contract documents.

5.14.4—Corrosion-Resistant Reinforcement

Protection of steel against chloride-induced corrosion may be provided by epoxy coating or galvanizing of reinforcing steel, post-tensioning duct, and anchorage hardware and by epoxy coating of prestressing strand or by using corrosion-resistant reinforcement bars complying with AASHTO M 334M/M 334.

Protection of concrete may include coatings such as silane sealer, methacrylate sealers and bituminous coatings for underground concrete.

5.14.5—Deck Protection Systems

Deck protection systems shall be considered for all bridge decks exposed to freeze-thaw cycles and application of deicing chemicals. The Owner should consider providing additional protection against penetration of chlorides. For segmental bridges the Owner should consider additional concrete cover acting as an integral wearing surface or a minimum 1.5 in. thickness overlay. If an integral overlay is selected, the Owner should consider an additional 0.5 in. of cover as a grinding allowance for rideability. Alternatively, a waterproof membrane with bituminous overlay or a noncementitious overlay may be used. The Owner may require specific materials and placement techniques stipulated by local practices.

5.14.6—Protection for Prestressing Tendons

Ducts for internal post-tensioned tendons, designed to provide bonded resistance, shall be grouted after stressing. Other tendons shall be permanently protected against corrosion and the details of protection shall be indicated in the contract documents.

Specify the PL of the PTS per Article C2.5.2.1.1.

C5.14.4

Specifications for acceptable epoxy coatings are included in the materials section of the *AASHTO LRFD Bridge Construction Specifications*. Other corrosion-resistant reinforcing bars meeting the requirements of AASHTO M 334M/M 334 have been increasingly used in bridge structures. Refer to Berke (2012), Darwin et al. (2009), Hartt et al. (2009), Salomon and Moen (2014), and Zhang et al. (2009).

C5.14.5

Deck protection systems are encouraged because they will add durability. The thickness of an integral overlay should be decided upon by the Owner considering local experience including the permeability of the concrete being used. Delamination of overlays is generally due to poor installation practices or material selection.

Careful attention to detail is required when using overlays to assure the proper railing heights are obtained. All railings next to deck areas to be overlaid should be detailed from the top of the overlay. See Article 13.7.3.2 for further information.

The need to remove and replace the overlay can be based on measurement of chloride penetration into the overlay. Use of high performance concrete is an effective means of minimizing chloride penetration into concrete.

Bridges located in other corrosive environments, such as coastal bridges over salt water, should be evaluated for the need for additional protection.

C5.14.6

Refer to Article C2.5.2.1.1 for information on selection of a PL.

In certain cases, such as longitudinal precast elements transversely post-tensioned together, the integrity of the structure does not depend on the bonded resistance of the tendons, but rather on the confinement provided by the prestressing elements. The unbonded tendons can be more readily inspected and replaced, one at a time, if so required.

External tendons have been successfully protected by cement grout in polyethylene ducts and metal pipes. Tendons have also been protected by heavy grease or other anticorrosion medium where future replacement is envisioned. Tendon anchorage regions should be protected by encapsulation or other effective means.

This is critical in unbonded tendons because any failure of the anchorage can release the entire tendon.

Where appropriate, replaceability of tendons may be considered and incorporated for either unbonded or grouted tendons. Access and details for future replaceability typically need to be considered in the original design. Information and details for replaceability of grouted tendons are available in Ledesma (2019).

 - 2. Multiple Presence (3.6.1.1.2)

APPENDIX B5—GENERAL PROCEDURE FOR SHEAR DESIGN WITH TABLES

B5.1—BACKGROUND

The general procedure herein is an acceptable alternative to the procedure specified in Article 5.7.3.4.2. The procedure in this Appendix utilizes tabularized values of β and θ instead of Eqs. 5.7.3.4.2-1, 5.7.3.4.2-2, and 5.7.3.4.2-3. Appendix B5 is a complete presentation of the general procedures in the AASHTO *LRFD Bridge Design Specifications* (2007) without any interim changes.

B5.2—SECTIONAL DESIGN MODEL— GENERAL PROCEDURE

For sections containing at least the minimum amount of transverse reinforcement specified in Article 5.7.2.5, the values of β and θ shall be as specified in Table B5.2-1. In using this table, ϵ_x shall be taken as the calculated longitudinal strain at the mid-depth of the member when the section is subjected to M_u , N_u , and V_u as shown in Figure B5.2-1.

For sections containing less transverse reinforcement than specified in Article 5.7.2.5, the values of β and θ shall be as specified in Table B5.2-2. In using this table, ϵ_x shall be taken as the largest calculated longitudinal strain which occurs within the web of the member when the section is subjected to N_u , M_u , and V_u as shown in Figure B5.2-2.

Where consideration of torsion is required by the provisions of Article 5.7.2, V_u in Eqs. B5.2-3 through B5.2-5 shall be replaced by V_{eff} .

For solid sections:

$$V_{eff} = \sqrt{V_u^2 + \left(\frac{0.9 p_h T_u}{2 A_o} \right)^2} \quad (\text{B5.2-1})$$

For hollow sections:

$$V_{eff} = V_u + \frac{T_u d_s}{2 A_o} \quad (\text{B5.2-2})$$

Unless more accurate calculations are made, ϵ_x shall be determined as:

- If the section contains at least the minimum transverse reinforcement as specified in Article 5.7.2.5:

$$\epsilon_x = \frac{\left(\frac{|M_u|}{d_v} + 0.5 N_u + 0.5 |V_u - V_p| \cot \theta - A_{ps} f_{ps} \right)}{2(E_s A_s + E_p A_{ps})} \quad (\text{B5.2-3})$$

CB5.2

The shear resistance of a member may be determined by performing a detailed sectional analysis that satisfies the requirements of Article 5.7.3.1. Such an analysis (see Figure CB5.2-1) would show that the shear stresses are not uniform over the depth of the web and that the direction of the principal compressive stresses changes over the depth of the beam. The more direct procedure given herein assumes that the concrete shear stresses are uniformly distributed over an area b_v wide and d_v deep, that the direction of principal compressive stresses (defined by angle θ) remains constant over d_v , and that the shear strength of the section can be determined by considering the biaxial stress conditions at just one location in the web. See Figure CB5.2-2.

For solid cross-section shapes, such as a rectangle or an “I,” there is the possibility of considerable redistribution of shear stresses. To make some allowance for this favorable redistribution it is safe to use a root-mean-square approach in calculating the nominal shear stress for these cross-sections, as indicated in Eq. B5.2-1. The 0.9 p_h comes from 90 percent of the perimeter of the spalled concrete section. This is similar to multiplying 0.9 times the lever arm in flexural calculations.

For a hollow girder, the shear flow due to torsion is added to the shear flow due to flexure in one exterior web, and subtracted from the opposite exterior web. In the controlling web, the second term in Eq. B5.2-2 comes from integrating the distance from the centroid of the section, to the center of the shear flow path around the circumference of the section. The stress is converted to a force by multiplying by the web height measured between the shear flow paths in the top and bottom slabs, which has a value approximately equal that of d_s . If the exterior web is sloped, this distance should be divided by the sine of the web angle from horizontal.

Members containing at least the minimum amount of transverse reinforcement have a considerable capacity to redistribute shear stresses from the most highly strained portion of the cross-section to the less highly strained portions. Because

The initial value of ϵ_x should not be taken greater than 0.001.

- If the section contains less than the minimum transverse reinforcement as specified in Article 5.7.2.5:

$$\epsilon_x = \frac{\left(\frac{|M_u|}{d_v} + 0.5N_u + 0.5|V_u - V_p| \cot \theta - A_{ps}f_{po} \right)}{E_s A_s + E_p A_{ps}} \quad (\text{B5.2-4})$$

The initial value of ϵ_x should not be taken greater than 0.002.

- If the value of ϵ_x from Eqs. B5.2-3 or B5.2-4 is negative, the strain shall be taken as:

$$\epsilon_x = \frac{\left(\frac{|M_u|}{d_v} + 0.5N_u + 0.5|V_u - V_p| \cot \theta - A_{ps}f_{po} \right)}{2(E_c A_{ct} + E_s A_s + E_p A_{ps})} \quad (\text{B5.2-5})$$

where:

- A_{ct} = area of concrete on the flexural tension side of the member as shown in Figure B5.2-1 (in.²)
- A_{ps} = area of prestressing steel on the flexural tension side of the member, as shown in Figure B5.2-1 (in.²)
- A_o = area enclosed by the shear flow path, including any area of holes therein (in.²)
- A_s = area of nonprestressed steel on the flexural tension side of the member at the section under consideration, as shown in Figure B5.2-1. In calculating A_s for use in this equation, bars which are terminated at a distance less than their development length from the section under consideration shall be ignored (in.²)
- d_s = distance from extreme compression fiber to the centroid of the nonprestressed tensile reinforcement (in.)
- f_{po} = a parameter taken as modulus of elasticity of prestressing steel multiplied by the locked-in difference in strain between the prestressing steel and the surrounding concrete. For the usual levels of prestressing, a value of $0.7f_{pu}$

of this capacity to redistribute, it is appropriate to use the mid-depth of the member as the location at which the biaxial stress conditions are determined. Members that contain no transverse reinforcement, or contain less than the minimum amount of transverse reinforcement, have less capacity for shear stress redistribution. Hence, for such members, it is appropriate to perform the biaxial stress calculations at the location in the web subject to the highest longitudinal tensile strain; see Figure B5.2-2.

The longitudinal strain at the mid-depth of the member, ϵ_x , can be determined by the procedure illustrated in Figure CB5.2-3. The actual section is represented by an idealized section consisting of a flexural tension flange, a flexural compression flange, and a web. The area of the compression flange is taken as the area on the flexure compression side of the member, i.e., the total area minus the area of the tension flange as defined by A_{ct} . After diagonal cracks have formed in the web, the shear force applied to the web concrete, $V_u - V_p$, will primarily be carried by diagonal compressive stresses in the web concrete. These diagonal compressive stresses will result in a longitudinal compressive force in the web concrete of $(V_u - V_p) \cot \theta$. Equilibrium requires that this longitudinal compressive force in the web needs to be balanced by tensile forces in the two flanges, with half the force, that is $0.5(V_u - V_p) \cot \theta$, being taken by each flange. To avoid a trial and error iteration process, it is a convenient simplification to take this flange force due to shear as $V_u - V_p$. This amounts to taking $0.5 \cot \theta = 1.0$ in the numerator of Eqs. B5.2-3, B5.2-4, and B5.2-5. This simplification is not expected to cause a significant loss of accuracy. After the required axial forces in the two flanges are calculated, the resulting axial strains, ϵ_t and ϵ_c , can be calculated based on the axial force-axial strain relationship shown in Figure CB5.2-4.

For members containing at least the minimum amount of transverse reinforcement, ϵ_x can be taken as:

$$\epsilon_x = \frac{\epsilon_t + \epsilon_c}{2} \quad (\text{CB5.2-1})$$

where ϵ_t and ϵ_c are positive for tensile strains and negative for compressive strains. If, for a member subject to flexure, the strain ϵ_c is assumed to be negligibly small, then ϵ_x becomes one half of ϵ_t . This is the basis for the expression for ϵ_x given in Eq. B5.2-3. For members containing less than the minimum amount of transverse reinforcement, Eq. B5.2-4 makes the conservative simplification that ϵ_x is equal to ϵ_t .

In some situations, it will be more appropriate to determine ϵ_x using the more accurate procedure of Eq. CB5.2-1 rather than the simpler Eqs. B5.2-3 through B5.2-5. For example, the shear capacity of sections near the ends of precast, pretensioned simple

- will be appropriate for both pretensioned and post-tensioned members (ksi)
- M_u = factored moment at the section, not to be taken less than $V_u d_v$ (kip-in.)
- N_u = factored axial force, taken as positive if tensile and negative if compressive (kip)
- p_h = perimeter of the centerline of the closed transverse torsion reinforcement (in.)
- T_u = applied factored torsional moment on the girder (kip-in.)
- V_u = factored shear force for the girder in Eq. B5.2-1 and for the web under consideration in Eq. B5.2-2 (kip)

Within the transfer length, f_{po} shall be increased linearly from zero at the location where the bond between the strands and concrete commences to its full value at the end of the transfer length.

The flexural tension side of the member shall be taken as the half-depth containing the flexural tension zone, as illustrated in Figure B5.2-1.

The crack spacing parameter as influenced by aggregate size, s_{xe} , used in Table B5.2-2, shall be determined as:

$$s_{xe} = s_x \frac{1.38}{a_g + 0.63} \leq 80 \text{ in.} \quad (\text{B5.2-6})$$

where:

- a_g = maximum aggregate size (in.)
- s_x = crack spacing parameter, taken as the lesser of either d_v or the maximum distance between layers of longitudinal crack control reinforcement, where the area of the reinforcement in each layer is not less than $0.003b_v s_x$, as shown in Figure B5.2-3 (in.)

In the evaluation of ϵ_x , β and θ , the following should be considered:

- M_u shall be taken as positive quantities and M_u shall not be taken less than $(V_u - V_p)d_v$.
- In calculating A_s and A_{ps} the area of bars or tendons which are terminated less than their development length from the section under consideration shall be reduced in proportion to their lack of full development.
- For sections closer than d_v to the face of the support, the value of ϵ_x calculated at d_v from the face of the support may be used in evaluating β and θ .
- If the axial tension is large enough to crack the flexural compression face of the section, the resulting increase in ϵ_x shall be taken into account. In lieu of more accurate calculations, the value calculated from Eq. B5.2-4 should be doubled.
- It is permissible to determine β and θ from Tables B5.2-1 and B5.2-2 using a value of ϵ_x that is

beams made continuous for live load will be estimated in a very conservative manner by Eqs. B5.2-3 through B5.2-5 because, at these locations, the prestressing strands are located on the flexural compression side and, therefore, will not be included in A_{ps} . This will result in the benefits of prestressing not being accounted for by Eqs. B5.2-3 through B5.2-5.

Absolute value signs were added to Eqs. B5.2-3 through B5.2-5 in 2004. This notation replaced direction in the nomenclature to take M_u and V_u as positive values. For shear, absolute value signs in Eqs. B5.2-3 through B5.2-5 are needed to properly consider the effects due to V_u and V_p in sections containing a parabolic tendon path which may not change signs at the same location as shear demand, particularly at midspan.

For pretensioned members, f_{po} can be taken as the stress in the strands when the concrete is cast around them, i.e., approximately equal to the jacking stress. For post-tensioned members, f_{po} can be conservatively taken as the average stress in the tendons when the posttensioning is completed.

Note that in both Table B5.2-1 and Table B5.2-2, the values of β and θ given in a particular cell of the table can be applied over a range of values. Thus from Table B5.2-1, $\theta = 34.4$ degrees and $\beta = 2.26$ can be used provided that ϵ_x is not greater than 0.75×10^{-3} and v_u/f'_c is not greater than 0.125. Linear interpolation between the values given in the tables may be used, but is not recommended for hand calculations. Assuming a value of ϵ_x larger than the value calculated using Eqs. B5.2-3, B5.2-4, or B5.2-5, as appropriate, is permissible and will result in a higher value of θ and a lower value of β . Higher values of θ will typically require more transverse shear reinforcement, but will decrease the tension force required to be resisted by the longitudinal reinforcement. Figure CB5.2-5 illustrates the shear design process by means of a flow chart. This figure is based on the simplified assumption that $0.5 \cot \theta = 1.0$.

greater than that calculated from Eqs. B5.2-4 and B5.2-5.

Figure B5.2-1—Illustration of Shear Parameters for Section Containing at Least the Minimum Amount of Transverse Reinforcement, $V_p = 0$

Figure B5.2-2—Longitudinal Strain, ϵ_x , for Sections Containing Less than the Minimum Amount of Transverse Reinforcement

Figure B5.2-3—Definition of Crack Spacing Parameter, s_x

For sections containing a specified amount of transverse reinforcement, a shear-moment interaction diagram, see Figure CB5.2-6, can be calculated directly from the procedures in this article. For a known concrete strength and a certain value of ϵ_x , each cell of Table B5.2-1 corresponds to a certain value of v_u/f'_c , i.e., a certain value of V_n . This value of V_n requires an amount of transverse reinforcement expressed in terms of the parameter $A_v f_y / (b_v s)$. The shear capacity corresponding to the provided shear reinforcement can be found by linearly interpolating between the values of V_n corresponding to two consecutive cells where one cell requires more transverse reinforcement than actually provided and the other cell requires less reinforcement than actually provided. After V_n and θ have been found in this manner, the corresponding nominal flexural resistance, M_n , can be found by calculating, from Eqs. B5.2-3 through B5.2-5, the moment required to cause this chosen value of ϵ_x , and calculating, from Eq. 5.7.3.5-1, the moment required to yield the reinforcement. The predicted moment capacity will be the lower of these two values. In using Eqs. 5.7.2.8-1, 5.7.3.5-1, and Eqs. B5.2-3 through B5.2-5 of the procedure to calculate a $V_n - M_n$ interaction diagram, it is appropriate to replace V_u by V_n , M_u by M_n , and N_u by N_n and to take the value of ϕ as 1.0. With an appropriate spreadsheet, the use of shear-moment interaction diagrams is a convenient way of performing shear design and evaluation.

The values of β and θ listed in Table B5.2-1 and Table B5.2-2 are based on calculating the stresses that can be transmitted across diagonally cracked concrete. As the cracks become wider, the stress that can be transmitted decreases. For members containing at least the minimum amount of transverse reinforcement, it is assumed that the diagonal cracks will be spaced about 12.0 in. apart. For members without transverse reinforcement, the spacing of diagonal cracks inclined at θ degrees to the longitudinal reinforcement is assumed to be $s_x / \sin \theta$, as shown in Figure B5.2-3. Hence, deeper members having larger values of s_x are calculated to have more widely spaced cracks and hence, cannot transmit such high shear stresses. The ability of the crack surfaces to transmit shear

stresses is influenced by the aggregate size of the concrete. Members made from concretes that have a smaller maximum aggregate size will have a larger value of s_{xc} and hence, if there is no transverse reinforcement, will have a smaller shear strength.

Notes:

1. Applies to all subarticles of the listed Article
2. Article 5.1 establishes the upper limit for the specified design compressive strength of lightweight concrete as 10.0 ksi for all Articles in Section 5.

**APPENDIX D5—ARTICLES MODIFIED TO ALLOW THE USE OF REINFORCEMENT
WITH A SPECIFIED MINIMUM YIELD STRENGTH UP TO 100 KSI**

Article	Brief Summary of Changes
5.2—DEFINITIONS	Modified the definition of tension-controlled section by changing “0.005” to “tension-controlled strain limit.” Added definition of tension-controlled strain limit.
5.3—NOTATION	Modified the definition of f_y to allow higher yield strengths. Added definitions of ϵ_{cl} and ϵ_{tl} , compression- and tension-controlled strain limits, respectively.
5.4.3.1 and C5.4.3.1—General	Permits the use of reinforcement with specified minimum yield strengths up to 100 ksi where allowed by specific articles.
5.4.3.2—Modulus of Elasticity	$E_s = 29,000$ ksi may be used for specified minimum yield strengths up to 100 ksi.
5.4.3.3 and C5.4.3.3—Special Applications	Permits the use of reinforcement with specified minimum yield strengths up to 100 ksi for elements in Seismic Zone 1.
5.5.3.2 and C5.5.3.2—Reinforcing Bars and Welded Wire Reinforcement	Modifies the fatigue equation for reinforcing bars to allow the equation to be used for specified minimum yield strengths up to 100 ksi.
5.5.4.2 and C5.5.4.2—Resistance Factors	Allows the use of reinforcement with specified minimum yield strengths up to 100 ksi for elements in Seismic Zone 1. Modifies the equation, figure, and commentary for ϕ . These now use ϵ_{cl} and ϵ_{tl} (compression- and tension-controlled strain limits) in place of 0.002 and 0.005.
5.6 and C5.6—DESIGN FOR FLEXURAL AND AXIAL FORCE EFFECTS - B REGIONS	Allows the use of reinforcement with specified minimum yield strengths up to 100 ksi for elements in Seismic Zone 1.
5.6.2.1 and C5.6.2.1—General	Keeps compression-controlled strain limit of 0.002 for reinforcement with specified minimum yield strengths up to 60.0 ksi and tension-controlled strain limit of 0.005 for reinforcement with specified minimum yield strengths up to 75.0 ksi. Provides compression- and tension-controlled strain limits of 0.004 and 0.008 for reinforcement with a specified minimum yield strength equal to 100 ksi. Linear interpolation is used for reinforcement with specified minimum yield strengths between 60.0 or 75.0 and 100 ksi. Equations are provided for where f_y may replace f_s or f_s' in Article 5.6.3.1 and Article 5.6.3.2.

Article	Brief Summary of Changes
5.6.3.2.5—Strain Compatibility Approach	Limits the steel stress in a strain compatibility calculation to the specified minimum yield strength.
5.6.3.4 and C5.6.3.4—Moment Redistribution	Adjusts strain limit to allow moment redistribution in structures using reinforcement with specified minimum yield strengths up to 100 ksi.
C5.6.4.4—Factored Axial Resistance	Warns that designs should consider that columns using higher strength reinforcing steel may be smaller and have lower axial stiffness.
5.6.4.6—Spirals, hoops and Ties	Permits spirals and ties made of reinforcement with specified minimum yield strengths up to 100 ksi for elements in Seismic Zone 1.
5.6.7 and C5.6.7—Control of Cracking by Distribution of Reinforcement	Limits f_{ss} to $0.6f_y$ (ksi) in Eq. 5.6.7-1. Only Class 1 requirement needs to be satisfied with greater corrosion resistant reinforcement.
5.7.2.4 and C5.7.2.4—Types of Transverse Reinforcement 5.7.2.5 and C5.7.2.5—Minimum Transverse Reinforcement	Permits transverse reinforcement with specified minimum yield strengths up to 100 ksi in applications with flexural shear without torsion.
C5.7.2.6—Maximum Spacing of Transverse Reinforcement	Indicates that spacing requirements have been verified for transverse reinforcement with specified minimum yield strengths up to 100 ksi in applications of shear without torsion.
5.7.2.7 and C5.7.2.7—Design and Detailing Requirements.	Permits transverse reinforcement with specified minimum yield strengths up to 100 ksi in applications with flexural shear without torsion.
C5.7.3.3—Nominal Shear Resistance	Identifies that transverse reinforcement with specified minimum yield strengths up to 100 ksi may be used in applications with flexural shear without torsion.
5.7.3.5 and C5.7.3.5—Longitudinal Reinforcement	Permits longitudinal reinforcing steel with specified minimum yield strengths up to 100 ksi.
5.7.4.2—Minimum Area of Interface Reinforcement	Clarifies that f_y is limited to 60.0 ksi in Eq. 5.7.4.2-1.
5.10.2 and C5.10.2 Hooks and Bends	Permits hooks with specified minimum yield strengths up to 100 ksi with transverse confining steel for elements in Seismic Zone 1.
5.10.4.1 and C5.10.4.1—Transverse Reinforcement for Compression Members, General	Permits spirals with specified minimum yield strengths up to 100 ksi for elements in Seismic Zone 1.
5.10.8.1.1—Basic Requirements 5.10.8.2 —Development of Reinforcement	Permits the development length equations to be used for reinforcement with specified minimum yield strengths up to 100 ksi.

Article	Brief Summary of Changes
5.10.8.2.1 Deformed Bars and Deformed Wire in Tension	Requires transverse confining steel for development of reinforcement with specified minimum yield strengths greater than 75.0 ksi.
5.10.8.2.4—Standard Hooks in Tension	Requires the use of modification factors or ties for hooks of reinforcement with specified minimum yield strengths exceeding 75.0 ksi.
5.10.8.4 and add C5.10.8.4—Splices of Bar Reinforcement	Permits splices in reinforcement with specified minimum yield strengths up to 100 ksi and requires transverse confining steel.
5.10.8.4.3a and C5.10.8.4.3a—Lap Splices in Tension	Requires transverse confining steel in splices of reinforcement with specified minimum yield strengths exceeding 75.0 ksi.
5.11.1—General	Permits the use of reinforcement with specified minimum yield strengths up to 100 ksi for elements in Seismic Zone 1.

SECTION 6

STEEL STRUCTURES

Commentary is opposite the text it annotates.

6.1—SCOPE

This Section addresses the design of steel components, splices, and connections for straight or horizontally curved beam and girder structures, frames, trusses and arches, cable-stayed and suspension systems, and metal deck systems, as applicable.

When applied to curved steel girders, these provisions shall be taken to apply to the design and construction of highway superstructures with horizontally curved steel I-shaped or single-cell box-shaped longitudinal girders with radii greater than 100 ft. Exceptions to this limit shall be based on a thorough evaluation of the application of the bridge under consideration consistent with structural fundamentals.

An outline of the steps for the design of steel-girder bridges is presented in Appendix C6.

C6.1

The LRFD provisions have no span limit. There has been a history of construction problems associated with curved bridges with spans greater than about 350 ft. Large girder self-weight may cause critical stresses and deflections during erection when the steel work is incomplete. Large lateral deflections and girder rotations associated with longer spans tend to make it difficult to fit up cross-frames. Large curved steel bridges have been built successfully; however, these bridges deserve special considerations such as the possible need for more than one temporary support in large spans.

Most of the provisions for proportioning main elements are grouped by structural action:

- Tension and combined axial tension, flexure, and flexural and/or torsional shear (Article 6.8)
- Compression and combined axial compression, flexure, and flexural and/or torsional shear (Article 6.9)
- Flexure, flexural shear, and torsion:
 - I-sections (Article 6.10)
 - Composite box sections (Article 6.11)
 - Noncomposite box sections and other miscellaneous sections (Article 6.12)

Provisions for connections and splices are contained in Article 6.13.

Article 6.14 contains provisions specific to particular assemblages or structural types, e.g., through-girder spans, trusses, orthotropic deck systems, and arches.

For certain types of steel structures, benefits may be gained by applying advanced analysis methods for the design of the structure and/or its components. Using these methods, the member and structure stability are assessed using a second-order analysis directly considering initial geometric imperfections and residual stress effects. These methods provide greater rigor for consideration of innovative structural systems and member geometries. In addition, they provide capabilities for recognizing reserve capacities not addressed by the provisions of this Section. Using these procedures, the members may be checked for their local “cross-section level” resistance given refined estimates of the internal strength demands as influenced by the member and overall system stability effects. These types of capabilities typically would be applied by focusing on a limited set of potentially critical factored design load combinations. Hendy and Murphy (2007) discuss the application of these types of methods in the context of steel bridge design according to the Eurocodes. Advanced analysis methods are an area of continued evolution as computer hardware and software continue to grow in their power and capabilities. Generally, advanced

analysis procedures must be calibrated to established physical test results considering appropriate nominal initial geometric imperfections and residual stresses.

6.2—DEFINITIONS

Abutment—An end support for a bridge superstructure.

Aspect Ratio—In any rectangular configuration, the ratio of the lengths of the sides.

Beam—A structural member whose primary function is to transmit loads to the support primarily through flexure and shear. Generally, this term is used when the component is made of rolled shapes.

Beam Column—A structural member whose primary function is to resist both axial loads and bending moments.

Bend-Buckling Resistance—The maximum load that can be carried by a web plate without experiencing theoretical elastic local buckling due to bending.

Bent Cap—A steel beam extending across one or more columns, comprising the top of a bent for the bridge span above; also commonly called a cap beam, cross-girder, or pier cap. Common bent cap configurations include integral, non-integral stacked, non-integral in-line, hammerhead, and straddle bent caps.

Biaxial Bending—Simultaneous bending of a member or component about two perpendicular axes.

Bifurcation—The phenomenon whereby an ideally straight or flat member or component under compression may either assume a deflected position or may remain undeflected, or an ideally straight member under flexure may either deflect and twist out-of-plane or remain in its in-plane deflected position.

Bifurcation Analysis—An analysis used to determine the buckling or bifurcation load.

Block Shear Rupture—Failure of a bolted web connection of coped beams or any tension connection by the tearing out of a portion of a plate along the perimeter of the connecting bolts.

Bolt Assembly—The bolt, nut(s), and washer(s).

Box Flange—A flange that is connected to two webs. The flange may be a flat unstiffened plate, a stiffened plate, or a flat plate with reinforced concrete attached to the plate with shear connectors.

Bracing Member—A member intended to brace a main member, or part thereof, against lateral movement.

Buckling Load—The load at which an ideally straight member or component under compression assumes a deflected position.

Built-Up Member—A member made of structural steel elements that are welded, bolted, or riveted together.

Charpy V-Notch Impact Requirement—The minimum energy required to be absorbed in a Charpy V-notch test conducted at a specified temperature.

Charpy V-Notch Test—An impact test complying with AASHTO T 243M/T 243 (ASTM A673/A673M).

Chord Splice—A connection between two discontinuous chord members in a truss structure, which may occur within or outside of a gusset plate.

Clear Distance of Bolts—The distance between edges of adjacent bolt holes.

Clear End Distance of Bolts—The distance between the edge of a bolt hole and the end of a member.

Closed-Box Section—A flexural member having a cross-section composed of two vertical or inclined webs which has at least one completely enclosed cell. A closed-section member is effective in resisting applied torsion by developing shear flow in the webs and flanges.

Collapse Load—The load that can be borne by a structural member or structure just before failure becomes apparent.

Compact Flange—For a composite section in negative flexure or a noncomposite section, a discretely braced compression flange with a slenderness at or below which the flange can sustain sufficient strains such that the maximum potential flexural resistance is achieved prior to flange local buckling (FLB) having a statistically significant influence on the response, provided that sufficient lateral bracing requirements are satisfied to develop the maximum potential flexural resistance.

Compact Section—A composite section in positive flexure satisfying specific steel grade, web slenderness, and ductility requirements that is capable of developing a nominal resistance exceeding the moment at first yield, but not to exceed the plastic moment.

Compact Unbraced Length—For a composite section in negative flexure or a noncomposite section, the limiting unbraced length of a discretely braced compression flange at or below which the maximum potential flexural resistance can be achieved prior to lateral-torsional buckling (LTB) having a statistically significant influence on the response, provided that sufficient flange slenderness requirements are satisfied to develop the maximum potential flexural resistance.

Compact Web—For a composite section in negative flexure or a noncomposite section, a web with a slenderness at or below which the section can achieve a maximum flexural resistance equal to the plastic moment prior to web bend-buckling having a statistically significant influence on the response, provided that sufficient steel grade, ductility, flange slenderness and/or lateral bracing requirements are satisfied.

Component—A constituent part of a structure or member.

Composite Beam—A steel beam connected to a deck so that they respond to force effects as a unit.

Composite Column—A structural compression member consisting of either structural shapes embedded in concrete, or a steel tube filled with concrete designed to respond to force effects as a unit.

Composite Concrete-Filled Steel Tube (CFST)—A composite member consisting of a circular steel tube and concrete fill, which may be used for piers, columns, piles, or drilled shafts.

Composite Girder—A steel flexural member connected to a concrete slab so that the steel element and the concrete slab, or the longitudinal reinforcement within the slab, respond to force effects as a unit.

Compression-Diagonal System—The common representation of an X-type cross-frame in computer programs where both the tension and compression diagonals are considered active in bracing a longitudinal flexural component.

Connection—A weld or arrangement of bolts that transfers normal and/or shear stresses from one element to another.

Constant-Amplitude Fatigue Threshold—The nominal stress range below which a particular detail can withstand an infinite number of repetitions without fatigue failure.

Contiguous Cross-Frames/Diaphragms—Intermediate cross-frames or diaphragms arranged in a continuous line across an entire I-girder bridge cross-section.

Continuously Braced Flange—A flange encased in concrete or anchored by shear connectors for which flange lateral bending effects need not be considered. A continuously braced flange in compression is also assumed not to be subject to local or LTB.

Cracked Section—A composite section in which the concrete is assumed to carry no tensile stress.

Critical Load—The load at which bifurcation occurs as determined by a theoretical stability analysis.

Cross-Frame—A transverse truss framework connecting adjacent longitudinal flexural components or inside a tub section or closed box used to transfer and distribute vertical and lateral loads and to provide stability to the compression flanges. Sometimes synonymous with the term diaphragm.

Cross-Frame Strut—The top and bottom horizontal members of a cross-frame.

Cross-Section Distortion—Change in shape of the cross-section profile due to torsional loading.

Curved Girder—An I-, closed-box, or tub girder that is curved in a horizontal plane.

Deck—A component, with or without wearing surface, that supports wheel loads directly and is supported by other components.

Deck System—A superstructure, in which the deck is integral with its supporting components, or in which the effects of deformation of supporting components on the behavior of the deck is significant.

Deck Truss—A truss system in which the roadway is at or above the level of the top chord of the truss.

Detail Category—A grouping of components and details having essentially the same fatigue resistance.

Diaphragm—A vertically oriented solid transverse member connecting adjacent longitudinal flexural components or inside a closed-box or tub section to transfer and distribute vertical and lateral loads and to provide stability to the compression flanges.

Discontinuous Cross-Frames/Diaphragms—Intermediate cross-frames or diaphragms arranged in a discontinuous line across an I-girder bridge cross-section.

Discretely Braced Flange—A flange supported at discrete intervals by bracing sufficient to restrain lateral deflection of the flange and twisting of the entire cross-section at the brace points.

Distortion-Induced Fatigue—Fatigue effects due to secondary stresses not normally quantified in the typical analysis and design of a bridge.

Edge Distance of Bolts—The distance perpendicular to the line of force between the center of a hole and the edge of the component.

Effective Area—The reduced cross-sectional area of a member containing slender cross-section elements and/or any longitudinally stiffened plates to account for the influence of local buckling and post-buckling on the overall member axial compressive resistance, or the reduced cross-sectional area of a longitudinally stiffened compression flange in a flexural member to account for the postbuckling resistance of the flange element.

Effective Length—The equivalent length, Kl , used in compression formulas and determined by a bifurcation analysis.

Effective Length Factor—The ratio between the effective length and the unbraced length of the member measured between the centers of gravity of the bracing members.

Effective Net Area—Net area modified to account for the effect of shear lag.

Effective Span—A defined span length used in the calculation of shear-lag effects.

Effective Width—The reduced width of a plate or concrete slab which, with an assumed uniform stress distribution, produces the same effect on the behavior of a structural member as the actual plate width with its nonuniform stress distribution.

Elastic—A structural response in which stress is directly proportional to strain and no deformation remains upon removal of loading.

Elastic Analysis—Determination of load effects on members and connections based on the assumption that the material stress–strain response is linear and the material deformation disappears on removal of the force that produced it.

Elastic-Perfectly Plastic (Elastic-Plastic)—An idealized material stress–strain curve that varies linearly from the point of zero strain and zero stress up to the yield point of the material, and then increases in strain at the value of the yield stress without any further increases in stress.

End Distance of Bolts—The distance along the line of force between the center of a hole and the end of the component.

End Panel—The end section of a truss or a web panel adjacent to a discontinuous end of the member.

Engineer—A licensed structural engineer responsible for the design of the bridge or review of the bridge construction.

Eyebar—A tension member with a rectangular section and enlarged ends for a pin connection.

Factored Load—The product of the nominal load and a load factor.

Fastener—Generic term for welds, bolts, rivets, or other connecting devices.

Fatigue—The initiation and/or propagation of cracks due to a repeated variation of normal stress with a tensile component.

Fatigue Design Life—The number of years that a detail is expected to resist the assumed traffic loads without fatigue cracking. In the development of these Specifications, it has been taken as 75 years.

Fatigue Life—The number of repeated stress cycles that results in fatigue failure of a detail.

Fatigue Resistance—The maximum stress range that can be sustained without failure of the detail for a specified number of cycles.

Finite Fatigue Life—The number of cycles to failure of a detail when the maximum probable stress range exceeds the constant-amplitude fatigue threshold.

First-Order Analysis—Analysis in which equilibrium conditions are formulated on the undeformed structure; that is, the effect of deflections is not considered in writing equations of equilibrium.

Fit Condition—The deflected girder geometry in which the cross-frames or diaphragms are detailed to connect to the girders.

Flange Extensions—Extensions of the flange(s) of a box-section member, measured from the outside surface of the webs, to allow for welding of the flange(s) to the webs.

Flange Lateral Bending—Bending of a flange about an axis perpendicular to the flange plate due to lateral loads applied to the flange and/or nonuniform torsion in the member.

Flange Local Buckling (FLB)—Limit state of buckling of a compression flange within a cross-section.

Flexural Buckling—A buckling mode in which a compression member deflects laterally without twist or change in cross-sectional shape.

Flexural-Torsional Buckling—A buckling mode in which a compression member bends and twists simultaneously without a change in cross-sectional shape.

Force—Resultant of distribution of stress over a prescribed area. Generic term signifying axial loads, bending moment, torques, and shears.

Fracture Control (FC) Practice—Practice required for materials and fabrication of NSTMs, newly designed SRMs, and primary plate components in newly designed IRMs. For flexural members, FC practice only applies in the portions of

the member located in designated tension zones under Strength Load Combination I where the preceding classifications apply.

Fracture Toughness—A measure of the ability of a structural material or element to absorb energy without fracture. It is generally determined by the Charpy V-notch test.

Gauge of Bolts—The distance between adjacent lines of bolts; the distance from the back of an angle or other shape to the first line of bolts.

Girder—A structural component whose primary function is to resist loads in flexure and shear. Generally, this term is used for fabricated sections.

Global LTB—Buckling mode in which a system of girders buckle as a unit with an unbraced length equal to the clear span of the girders.

Grip—Distance between the nut and the bolt head.

Gusset Plate—Plate material used to interconnect vertical, diagonal, and horizontal truss members at a panel point, or to interconnect diagonal and horizontal cross-frame members for subsequent attachment of the cross-frame to transverse connection plates.

Half Through-Truss Spans—A truss system with the roadway located somewhere between the top and bottom chords. It precludes the use of a top lateral system.

Hollow Structural Sections (HSS)—Square, rectangular, or hollow structural steel sections produced in accordance with a pipe or tubing product specification.

Hybrid Section—A fabricated steel section with a web that has a specified minimum yield strength lower than one or both flanges.

Inelastic Action—A condition in which deformation is not fully recovered upon removal of the load that produced it.

Inelastic Redistribution—The redistribution of internal force effects in a component or structure caused by inelastic deformations at one or more sections.

Instability—A condition reached in the loading of a component or structure in which continued deformation results in a decrease of load-resisting capacity.

Interior Panel—The interior section of a truss or a web panel not adjacent to a discontinuous end of the member.

Internal Redundancy—A redundancy that exists within a primary member cross-section without load path redundancy, such that fracture of one component will not propagate through the entire member, is discoverable by the applicable inspection procedures, and will not cause a portion of or the entire bridge to collapse.

Internally Redundant Member (IRM)—A primary built-up steel member fully or partially in tension, that has internal redundancy.

Joint—Area where two or more ends, surfaces, or edges are attached. Categorized by type of fastener used and method of force transfer.

Lacing—Plates or bars to connect components of a member.

Lateral Bending Stress—The normal stress caused by flange lateral bending.

Lateral Bracing—A truss placed in a horizontal plane between two I-girders or two flanges of a tub girder to maintain cross-sectional geometry, and provide additional stiffness and stability to the bridge system.

Lateral Bracing Component—A component utilized individually or as part of a lateral bracing system to prevent buckling of components and/or to resist lateral loads.

Lateral Connection Plate—A plate used to interconnect lateral bracing members for attachment to a flexural member.

Lateral-Torsional Buckling (LTB)—Buckling of a component involving lateral deflection and twist.

Level—That portion of a rigid frame that includes one horizontal member and all columns between that member and the base of the frame or the next lower horizontal member.

Limit State—A condition in which a component or structure becomes unfit for service and is judged either to be no longer useful for its intended function or to be unsafe. Limits of structural usefulness include brittle fracture, plastic collapse, excessive deformation, durability, fatigue, instability, and serviceability.

Load Effect—Moment, shear, axial force, or torque induced in a member by loads applied to the structure.

Load Path—A succession of components and joints through which a load is transmitted from its origin to its destination.

Load-Path Redundancy—A redundancy that exists based on the number of primary load-carrying members between points of support, such that fracture of the cross-section at one location of a member will not cause a portion of or the entire bridge to collapse.

Load Path Redundant Member (LPRM)—A primary steel member fully or partially in tension, that has load path redundancy.

Load-Induced Fatigue—Fatigue effects due to the in-plane stresses for which components and details are explicitly designed.

Local Buckling—The buckling of a plate element in compression.

Locked-In Forces—The internal forces induced into a I-girder structural system when Steel Dead-Load Fit (SDLF) or Total Dead-Load Fit (TDLF) detailing is employed. These internal forces are caused by the lack-of-fit detailed between the cross-frames and the girders in the base fully cambered No-Load (NL) geometry. These internal forces would remain if the structure's dead loads were theoretically removed.

Longitudinally Loaded Weld—Weld with applied stress parallel to the longitudinal axis of the weld.

Longitudinally Stiffened Plate Panel—The portion of a longitudinally stiffened plate bounded in the width direction by the centerlines of individual longitudinal stiffeners or the centerline of a longitudinal stiffener and the inside of the laterally restrained longitudinal edge of a longitudinally stiffened plate, and bounded in the length direction by diaphragms and/or transverse stiffeners.

Longitudinal Stiffener—A stiffener attached along the length of a component plate of a member to provide additional local and overall compressive resistance to that component.

Major Axis—The centroidal axis about which the moment of inertia is a maximum; also referred to as the “major principal axis.”

Net Tensile Stress—The algebraic sum of two or more stresses in which the total is tension.

No-Load Fit (NLF) Detailing—A method of detailing in which the cross-frames or diaphragms are detailed such that their connection work points fit with the corresponding work points on the girders without any force-fitting, with the girders assumed erected in their fully cambered (plumb) geometry under zero load. NLF detailing is also synonymously referred to as “fully cambered fit detailing.”

Noncompact Flange—For a composite section in negative flexure or a noncomposite section, a discretely braced compression flange with a slenderness at or below the limit at which localized yielding within the member cross-section

associated with a hybrid web, residual stresses and/or cross-section monosymmetry has a statistically significant effect on the nominal flexural resistance.

Noncompact Section—A composite section in positive flexure for which the nominal resistance is not permitted to exceed the moment at first yield.

Noncompact Unbraced Length—For a composite section in negative flexure or a noncomposite section, the limiting unbraced length of a discretely braced compression flange at or below the limit at which the onset of yielding in either flange of the cross-section with consideration of compression-flange residual stress effects has a statistically significant effect on the nominal flexural resistance.

Noncompact Web—For a composite section in negative flexure or a noncomposite section, a web satisfying steel grade requirements and with a slenderness at or below the limit at which theoretical elastic web bend-buckling does not occur for elastic stress values, computed according to beam theory, smaller than the limit of the nominal flexural resistance.

Noncomposite Section—A steel beam where the deck is not connected to the steel section by shear connectors.

Nonprismatic Unbraced Length—An unbraced length between cross-frames or diaphragms in which the member cross-section varies along the length.

Nonredundant Steel Tension Member (NSTM)—A primary steel member fully or partially in tension, and without load path redundancy, system redundancy or internal redundancy, whose failure may cause a portion of or the entire bridge to collapse.

Nonslender Cross-Section Element—A longitudinally unstiffened plate element within the cross-section of a member having a slenderness small enough such that the element is able to develop its full nominal yield strength in uniform axial compression without any reduction due to local buckling.

Nonuniform Torsion—An internal resisting torsion in thin-walled sections, also known as warping torsion, producing shear stress and normal stresses, and under which cross-sections do not remain plane. Members developing nonuniform torsion resist the externally applied torsion by warping torsion and St. Venant torsion. Each of these components of internal resisting torsion varies along the member length, although the externally applied concentrated torsion may be uniform along the member between two adjacent points of torsional restraint. Warping torsion is dominant over St. Venant torsion in members having open cross-sections, whereas St. Venant torsion is dominant over warping torsion in members having closed cross-sections.

Open Section—A flexural member having a cross-section which has no enclosed cell. An open-section member resists torsion primarily by nonuniform torsion, which causes normal stresses at the flange tips.

Orthotropic Deck—A deck made of a steel plate stiffened with open or closed steel ribs welded to the underside of a steel plate.

Permanent Deflection—A type of inelastic action in which a deflection remains in a component or system after the load is removed.

Phased Construction—Construction in which a bridge is built in separate units with a longitudinal construction joint between them.

Pier—A column or connected group of columns or other configuration designed to be an interior support for a bridge superstructure.

Pitch—The distance between the centers of adjacent bolt holes or shear connectors along the line of force.

Plastic Analysis—Determination of load effects on members and connections based on the assumption of rigid-plastic behavior; i.e., that equilibrium is satisfied throughout the structure and yield is not exceeded anywhere. Second-order effects may need to be considered.

Plastic Hinge—A yielded zone which forms in a structural member when the plastic moment is attained. The beam is assumed to rotate as if hinged, except that the plastic moment capacity is maintained within the hinge.

Plastic Moment—The resisting moment of a fully yielded cross-section.

Plastic Strain—The difference between total strain and elastic strain.

Plastic Stress Distribution Method (PSDM)—An equilibrium method using full yield strength of the steel in tension and compression, and a uniform concrete stress distribution with a magnitude of stress equal to $0.95f'_c$ over the entire compressive region, to determine a nominal material-based P-M interaction curve for CFST members without consideration of buckling.

Plastification—The process of successive yielding of fibers in the cross-section of a member as bending moment is increased.

Plate—A flat rolled product whose thickness exceeds 0.25 in.

Plateau Strength—The maximum potential flexural resistance of a compression flange based on either FLB or LTB defined by a plateau at flange slenderness values less than or equal to λ_{pf} or at unbraced lengths less than or equal to L_p , respectively.

Portal Frames—End transverse truss bracing or Vierendeel bracing to provide for stability and to resist wind or seismic loads.

Post-Buckling Resistance—The load that can be carried by a member or component after buckling.

Primary Member—A steel member or component that transmits gravity loads through a necessary as-designed load path. These members are therefore subjected to more stringent fabrication and testing requirements; considered synonymous with the term “main member.”

Prismatic Member—A member having a constant cross-section along its length.

Prismatic Unbraced Length—An unbraced length between cross-frames or diaphragms in which the member cross-section does not vary along the length.

Prying Action—Lever action that exists in connections in which the line of application of the applied load is eccentric to the axis of the bolt, causing deformation of the fitting and an amplification of the axial force in the bolt.

Redistribution Moment—An internal moment caused by yielding in a continuous-span bending component and held in equilibrium by external reactions.

Redistribution of Moments—A process that results from formation of inelastic deformations in continuous structures.

Redistribution Stress—The bending stress resulting from the redistribution moment.

Redundancy—The quality of a bridge that enables it to perform its design function in a damaged state.

Redundant Member—A member whose failure does not cause failure of the bridge.

Regularly Spaced Shear Connectors—Shear connectors that are placed in approximately equidistant intervals within one or more regions along the longitudinal axis of the beam or girder.

Required Fatigue Life—A product of the single-lane average daily truck traffic, the number of cycles per truck passage, and the design life in days.

Residual Stress—The stresses that remain in an unloaded member or component after it has been formed into a finished product by cold bending, and/or cooling after rolling or welding.

Reverse Curvature Bending—A bending condition in which end moments on a member cause the member to assume an S shape.

Rigid Frame—A structure in which connections maintain the angular relationship between beam and column members under load.

St. Venant Torsion—That portion of the internal resisting torsion in a member producing only pure shear stresses on a cross-section, also referred to as “pure torsion” or “uniform torsion.”

Second-Order Analysis—Analysis in which equilibrium conditions are formulated on the deformed structure; that is, in which the deflected position of the structure is used in writing the equations of equilibrium.

Secondary Member—A steel member or component that does not transmit gravity loads through a necessary as-designed load path.

Service Loads—Loads expected to be supported by the structure under normal usage.

Shape Factor—The ratio of the plastic moment to the yield moment, or the ratio of the plastic section modulus to the elastic section modulus.

Shear Buckling Resistance—The maximum load that can be supported by a web plate without experiencing theoretical buckling due to shear.

Shear Connector—A mechanical device that prevents relative movements both normal and parallel to an interface.

Shear Connector Clusters—Repeated groupings of three or more equally spaced rows of shear stud connectors spaced at intervals along the longitudinal axis of the beam or girder.

Shear Flow—Shear force per unit width acting parallel to the edge of a plate element.

Shear Lag—Nonlinear distribution of normal stress across a component due to shear distortions.

Sheet—A flat rolled product whose thickness is between 0.006 and 0.25 in.

Single-Curvature Bending—A deformed shape of a member in which the center of curvature is on the same side of the member throughout the unbraced length.

Skew Angle—The angle between the axis of support relative to a line normal to the longitudinal axis of the bridge, i.e. a zero-degree skew denotes a rectangular bridge.

Slab—A deck composed of concrete and reinforcement.

Slender Cross-Section Element—A longitudinally unstiffened plate element within the cross-section of a member having a slenderness large enough such that nominal local buckling of the element may occur and may have an impact on its resistance in uniform axial compression prior to developing its full nominal yield strength.

Slender Flange—For a composite section in negative flexure or a noncomposite section, a discretely braced compression flange with a slenderness at or above which the nominal flexural resistance is governed by elastic FLB, provided that sufficient lateral bracing requirements are satisfied.

Slender Unbraced Length—For a composite section in negative flexure or a noncomposite section, the limiting unbraced length of a discretely braced compression flange at or above which the nominal flexural resistance is governed by elastic LTB.

Slender Web—For a composite section in negative flexure or a noncomposite section, a web with a slenderness at or above which the theoretical elastic bend-buckling stress in flexure is reached in the web prior to reaching the yield strength of the compression flange.

Slenderness Ratio—The ratio of the effective length of a member to the radius of gyration of the member cross-section, both with respect to the same axis of bending, or the full or partial width or depth of a component divided by its thickness.

Splice—A group of bolted connections, or a welded connection, sufficient to transfer the moment, shear, axial force, or torque between two structural elements joined at their ends to form a single, longer element.

Stay-in-Place Formwork—Permanent metal or precast concrete forms that remain in place after construction is finished.

Staged Deck Placement—Placement of a concrete bridge deck in successive stages with a longitudinal and/or transverse construction joint between them.

Steel Dead-Load Fit (SDLF) Detailing—A method of detailing in which the cross-frames or diaphragms are detailed such that their connection work points fit with the corresponding work points on the girders with the steel dead-load vertical deflections and the associated girder major-axis rotations at the connection plates subtracted from the fully cambered geometry of the girders, and with the girder webs assumed in an ideal plumb position under the Steel Dead Load (SDL) at the completion of the steel erection. SDLF detailing is also synonymously referred to as “erected-fit detailing.”

Stiffener—A member, usually an angle or plate, attached to a plate or web of a beam or girder to distribute load, to transfer shear, or to prevent buckling of the member to which it is attached.

Stiffness—The resistance to deformation of a member or structure measured by the ratio of the applied force to the corresponding displacement.

Strain Compatibility Method (SCM)—An equilibrium method using strain compatibility-based stress distributions in concrete and steel to determine a nominal material-based P-M interaction curve of CFST members without consideration of buckling.

Strain Hardening—Phenomenon wherein ductile steel, after undergoing considerable deformation at or just above the yield point, exhibits the capacity to resist substantially higher loading than that which caused initial yielding.

Strain-Hardening Strain—For structural steels that have a flat or nearly flat plastic region in the stress-strain relationship, the value of the strain at the onset of strain hardening.

Stress Range—The algebraic difference between extreme stresses resulting from the passage of a load.

Strong Axis—The centroidal axis about which the moment of inertia is a maximum.

Subpanel—A stiffened web panel divided by one or more longitudinal stiffeners.

Sway Bracing—Transverse vertical bracing between truss members.

System Redundancy—A redundancy that exists in a bridge system without load path redundancy, such that fracture of the cross-section at one location of a primary member will not cause a portion of or the entire bridge to collapse.

System Redundant Member (SRM)—A primary steel member fully or partially in tension, that has system redundancy.

Tensile Strength—The maximum tensile stress that a material is capable of sustaining.

Tension-Field Action—The behavior of a girder panel under shear in which diagonal tensile stresses develop in the web and compressive forces develop in the transverse stiffeners in a manner analogous to a Pratt truss.

Tension-Only Diagonal System—An idealized representation of an X-type cross-frame where the compression diagonal is conservatively neglected. The tension diagonal and the top and bottom struts are considered active in bracing a longitudinal flexural component.

Through-Girder Spans—A girder system where the roadway is below the top flange.

Through-Thickness Stress—Bending stress in a web or box flange induced by distortion of the cross-section.

Through-Truss Spans—A truss system where the roadway is located near the bottom chord and where a top chord lateral system is provided.

Tie Plates—Plates used to connect components of a member.

Tied Arch—An arch in which the horizontal thrust of the arch rib is resisted by a horizontal tie.

Toe of the Fillet—Termination point of a fillet weld or a rolled-section fillet.

Torsional Buckling—A buckling mode in which a compression member twists about its shear center.

Torsional Shear Stress—Shear stress induced by St. Venant torsion.

Total Dead Load Fit (TDLF) Detailing—A method of detailing in which the cross-frames or diaphragms are detailed such that their connection work points fit with the corresponding work points on the girders with the total dead load vertical deflections and the associated girder major-axis rotations at the connection plates subtracted from the fully cambered geometry of the girders, and with the girder webs assumed in an ideal plumb position under the Total Dead Load (TDL). TDLF detailing is also synonymously referred to as “final-fit detailing.”

Transverse Connection Plate—A vertical stiffener attached to a beam or girder to which a cross-frame, diaphragm, floorbeam, or stringer is connected.

Transverse Stiffener—A stiffener attached to a component plate normal to the longitudinal axis of the member to provide additional shear or axial compressive resistance.

Transversely Loaded Weld—Weld with applied stress perpendicular to the longitudinal axis of the weld.

Trough-Type Box Section—A U-shaped section without a common top flange.

True Arch—An arch in which the horizontal component of the force in the arch rib is resisted by an external force supplied by its foundation.

Tub Section—An open-topped steel girder which is composed of a bottom flange plate, two inclined or vertical web plates, and an independent top flange attached to the top of each web. The top flanges are connected with lateral bracing members.

Unbraced Length—Distance between brace points resisting the mode of buckling or distortion under consideration; generally, the distance between panel points or brace locations.

Von Mises Yield Criterion—A theory which states that the inelastic action at a point under a combination of stresses begins when the strain energy of distortion per unit volume is equal to the strain energy of distortion per unit volume in a simple tensile bar stressed to the elastic limit under a state of uniaxial stress. This theory is also called the “maximum strain-energy-of-distortion theory.” Accordingly, shear yield occurs at 0.58 times the yield strength.

Warping Stress—Normal stress induced in the cross-section by warping torsion and/or by distortion of the cross-section.

Warping Torsion—That portion of the total resistance to torsion in a member producing shear and normal stresses that is provided by resistance to out-of-plane warping of the cross-section.

Web Crippling—The local failure of a web plate in the immediate vicinity of a concentrated load or bearing reaction due to the transverse compression introduced by this load.

Web Panel—A length of girder web in-between adjacent transverse intermediate web stiffeners or a transverse intermediate web stiffener and a bearing stiffener. Web panels are classified as either end panels or interior panels.

Web Slenderness Ratio—The depth of a web between flanges divided by the web thickness.

Whitmore Section—A portion of a truss gusset plate defined at the end of a member fastener pattern based on 30 degree dispersion patterns from the lead fastener, through which it may be assumed for the purposes of design that all force from the member is evenly distributed into the gusset plate.

Yield Moment—In a member subjected to flexure, the moment at which an outer fiber first attains the yield stress.

Yield Strength—The stress at which a material exhibits a specified limiting deviation from the proportionality of stress to strain.

Yield Stress Level—The stress determined in a tension test when the strain reaches 0.005 in. per in.

6.3—NOTATION

$2a$	=	length of the nonwelded root face in the direction of the thickness of the loaded discontinuous plate element (in.); length of the nonwelded root face in the direction of the thickness of the loaded plate (in.). For fillet-welded connections, the quantity $(2a/t_p)$ shall be taken as equal to 1.0 (6.6.1.2.5)
A	=	detail category constant taken from Table 6.6.1.2.3-1 (ksi ^m); gross cross-sectional area of the box section, including any longitudinal stiffeners (in. ²); moment arm for calculating the moment resistance of the flanges at a point of splice (in.) (6.6.1.2.5) (6.12.2.2.2e) (C6.13.6.1.3b)
A_b	=	projected bearing area on a pin plate (in. ²); area of a single reinforcing bar in a composite concrete-filled steel tube (in. ²); area of the bolt corresponding to the nominal diameter (in. ²) (6.8.7.2) (C6.12.2.3.3) (6.13.2.7)
A_{bot}	=	area of the bottom flange (in. ²) (6.10.10.1.2)
A_c	=	gross cross-sectional area of the corner pieces of a noncomposite box-section member (in. ²); cross-sectional area of concrete (in. ²); net cross-sectional area of the concrete in a composite concrete-filled steel tube (in. ²); area of the concrete deck (in. ²) (6.9.4.2.2a) (6.9.5.1) (6.9.6.3.2) (D6.3.2)
A_d	=	gross cross-sectional area of cross-frame diagonal member (in. ²); minimum required cross-sectional area of a diagonal member of top lateral bracing for tub sections (in. ²) (6.7.4.2.2) (C6.7.5.3)
$ADTT$	=	average daily truck traffic over the design life (6.6.1.2.5)
$(ADTT)_{SL}$	=	single-lane $ADTT$ (6.6.1.2.3)
A_e	=	effective net area (in. ²); effective flange area (in. ²) (6.6.1.2.3) (6.13.6.1.3b)
A_{eff}	=	effective area of the cross-section taken as the summation of the effective areas of the cross-section elements determined as specified in Article 6.9.4.2.2a or E6.1.1, or determined as specified in Article 6.9.4.2.2c for circular tubes and round hollow structural sections (HSS) (in. ²); effective area of a longitudinally stiffened box flange located at the centroid of the gross area of the entire flange plate and its longitudinal stiffeners (in. ²); effective area of a longitudinally stiffened compression flange (in. ²) (6.9.4.2.2a) (6.11.8.2.3) (6.12.2.2.2d)
$(A_{eff})_{sp}$	=	effective area of a longitudinally stiffened plate, determined as specified in Article E6.1.3 (in. ²) (E6.1.1)
A_{eR}	=	effective tributary area of a laterally restrained longitudinal edge of the longitudinally stiffened plate under consideration (in. ²) (E6.1.3)
A_{es}	=	effective area of an individual stiffener strut (in. ²) (E6.1.3)
A_f	=	area of the inclined bottom flange (in. ²); sum of the area of fillers on both sides of a connecting plate (in. ²); area of flange transmitting a concentrated load (in. ²) (C6.10.1.4) (6.13.6.1.4) (6.13.7.2)
A_{fce}	=	effective compression flange area, including corners and flange extensions (in. ²) (C6.12.2.2.2)
A_{fn}	=	sum of the flange area and the area of any cover plates on the side of the neutral axis corresponding to D_n in a hybrid section (in. ²) (6.10.1.10.1)
A_{ft}	=	gross tension-flange area, including corners and flange extensions (in. ²) (C6.12.2.2.2)
A_g	=	gross area of a member (in. ²); gross cross-sectional area of the member (in. ²); total gross cross-sectional area of the member (in. ²); gross cross-sectional area of a tube (in. ²); gross area of the tension flange (in. ²); gross cross-sectional area of the effective Whitmore section determined based on 30 degree dispersion angles (in. ²); gross area of the section based on the design wall thickness (in.); gross area of the flange under consideration (in. ²); gross area of all plates in the cross-section intersecting the spliced plane (in. ²) (6.6.1.2.3) (6.8.2.1) (6.9.4.2.2a) (6.9.4.2.2c) (6.10.1.8) (6.12.1.2.3b) (6.13.6.1.3b) (6.14.2.8.4) (6.14.2.8.6)
A_{gf}	=	gross area of the tension flange (in. ²) (6.8.2.3.3)
A_{gR}	=	gross area of a laterally restrained longitudinal edge of a longitudinally stiffened plate (in. ²) (E6.1.3)
A_{gs}	=	gross area of an individual stiffener strut (in. ²) (E6.1.3)
A_n	=	net area of a member (in. ²); net cross-section area of a tension member (in. ²); net area of a flange (in. ²); net area of gusset and splice plates (in. ²) (6.6.1.2.3) (6.8.2.1) (6.10.1.8) (6.14.2.8.6)
A_{nc}	=	projected area of concrete for a single stud shear connector or group of connectors approximated from the base of a rectilinear geometric figure that results from projecting the failure surface outward $1.5h_h$ from the centerline of the single connector or, in the case of a group of connectors, from a line through a row of adjacent connectors (in. ²) (6.16.4.3)

A_{nco}	=	projected area of concrete failure for a single stud shear connector based on the concrete breakout resistance in tension (in. ²) (6.16.4.3)
A_{nf}	=	net area of the tension flange, determined as specified in Article 6.8.3 (in. ²) (6.8.2.3.3)
A_o	=	enclosed area within a box section (in. ²); cross-sectional area of the box-section member enclosed by the mid-thickness of the walls (in. ²); cross-sectional area of the box-section member enclosed by the mid-thickness of the walls, and concrete deck as applicable (C6.7.4.3) (6.11.3.2) (6.11.7.2.2)
A_p	=	smaller of either the connected plate area on the side of the connection with the filler, or the sum of the splice plate area on both sides of the connected plate (in. ²) (6.13.6.1.4)
A_{pm}	=	area of the projecting elements of a stiffener outside of the web-to-flange welds but not beyond the edge of the flange (in. ²) (6.10.11.2.3)
A_r	=	total cross-sectional area of the longitudinal reinforcement (in. ²) (6.9.5.1)
A_{rb}	=	area of the bottom layer of longitudinal reinforcement within the effective concrete deck width (in. ²) (D6.1)
A_{rs}	=	total area of the longitudinal reinforcement included in the composite section at a bolted field splice in a flexural member satisfying the size, spacing, and placement requirements specified in Article 6.10.1.7, but not to exceed one percent of the total cross-sectional area of the concrete deck assumed distributed within the appropriate effective width of the concrete deck acting with the girder under consideration (in. ²); total area of the longitudinal reinforcement within the effective concrete deck width (in. ²) (C6.13.6.1.3b) (D6.3.2)
A_{rt}	=	area of the top layer of longitudinal reinforcement within the effective concrete deck width (in. ²) (D6.1)
A_s	=	gross cross-sectional area of cross-frame strut member (in. ²); cross-sectional area of the steel section (in. ²); total area of longitudinal reinforcement over the interior support within the effective concrete deck width (in. ²); area of the concrete deck (in. ²); gross area of an individual longitudinal stiffener, excluding the tributary width of the longitudinally stiffened plate under consideration (in. ²) (6.7.4.2.2) (6.9.5.1) (6.10.10.3) (D6.3.2) (E6.1.3)
A_{sb}	=	total cross-sectional area of the internal reinforcement bars in a composite concrete-filled steel tube (in. ²) (6.9.6.3.2)
A_{sc}	=	cross-sectional area of a stud shear connector (in. ²) (6.10.10.2)
A_{st}	=	cross-sectional area of the steel tube in a composite concrete-filled steel tube (in. ²) (6.9.6.3.2)
A_t	=	area of the tension flange (in. ²) (D6.3.2)
A_{tn}	=	net area along the plane resisting tension stress (in. ²) (6.13.4)
A_v	=	cross-sectional area of transverse reinforcement that intercepts a diagonal shear crack in a concrete-encased shape (in. ²) (6.12.3.1)
A_{vg}	=	gross area along the plane resisting shear stress (in. ²); gross area of the connection element subject to shear (in. ²); gross area of gusset plate subject to shear (in. ²) (6.13.4) (6.13.5.3) (6.14.2.8.3)
A_{vn}	=	net area along the plane resisting shear stress (in. ²); net area of the connection element subject to shear (in. ²) (6.13.4) (6.13.5.3)
A_w	=	gross area of the webs (in. ²); area of the web of a steel section (in. ²); moment arm for calculating the horizontal force in the web for composite sections in positive flexure at a point of splice (in.) (6.12.2.2.2) (6.12.2.3.1) (C6.13.6.1.3c)
a	=	distance between connectors (in.); center-to-center distance between flanges of adjacent boxes in a multiple box section (in.); distance from the center of a bolt to the edge of a plate subject to a tensile force due to prying action (in.); the width of the closed rib at the deck plate, centerline rib plate to centerline rib plate (in.); longitudinal spacing between locations of transverse stiffeners or diaphragms that provide transverse lateral restraint to a longitudinally stiffened plate (in.) (6.9.4.3.1) (6.11.2.3) (6.13.2.10.4) (6.14.3.2.3) (E6.1.3)
a_{max}	=	largest of the longitudinal spacings to the adjacent transverse stiffeners or diaphragms providing lateral restraint to the plate (in.) (CE6.1.5.1)
a_{min}	=	smallest of the longitudinal spacings to the adjacent transverse stiffeners or diaphragms providing lateral restraint to the plate (in.) (E6.1.5.2)
a_{wc}	=	ratio of two times the web area in compression to the area of the compression flange (6.10.1.10.2)
B	=	overall width of rectangular HSS member, measured 90 degrees to the plane of the connection (in.); (6.8.2.2)
b	=	width of a rectangular plate element (in.); width of the body of an eyebar (in.); element width as specified in Table 6.9.4.2.1-1 (in.); the smaller of d_o and D (in.); clear projecting width of the box flange under consideration measured from the outside surface of the web (in.); clear projecting width of the flange under consideration measured from the outside surface of the web (in.); distance between the toe of the flange and the centerline of the web (in.); width of a concrete-encased shape perpendicular to the plane of flexure

	(in.); distance from the center of a bolt to the toe of the fillet of a connected part (in.); unsupported width of a cross-section plate component in an arch rib (in.); width of a longitudinally unstiffened plate (in.); longitudinal stiffener plate element width (in.) (C6.7.4.3) (6.7.6.3) (6.9.4.2.1) (6.10.11.1.3) (6.11.2.2) (6.12.2.2.2b) (6.12.2.2.5) (6.12.2.3.1) (6.13.2.10.4) (6.14.4.1) (E6.1.1) (E6.1.4)
b_1, b_2	= individual flange widths (in.) (C6.9.4.1.3)
b_c	= full width of the compression flange (in.) (D6.1)
b_e	= effective width of the element under consideration determined as specified in Article 6.9.4.2.2b for slender elements, and taken equal to b for nonslender elements (in.); effective width of a longitudinally unstiffened compression flange (in.); effective width of a longitudinally unstiffened plate (in.) (6.9.4.2.2a) (6.12.2.2.2g) (E6.1.1)
b_f	= full width of the flange (in.); flange width (in.); total inside width between the plate elements providing lateral restraint to the longitudinal edges of the flange plate element under consideration (in.); for I-sections, full width of the widest compression flange within the field section under consideration; for tub sections, full width of the widest top flange within the field section under consideration (in.); width of the single top flange under consideration (in.); flange width (in.). For double angles, b_f shall be taken as the full width of a single flange leg. (C6.7.4.2.1) (6.8.2.2) (6.9.4.5) (6.10.11.1.2) (6.11.2.2) (6.12.2.2.4d)
b_{fc}	= full width of the compression flange; width of the compression flange (in.); compression flange width between webs (6.10.1.10.2) (6.10.9.3.2) (6.11.8.2.2b)
b_{fce}	= effective width of the compression flange, including corners and flange extensions (in.) (C6.12.2.2.2c)
$b_{fc\ eff}$	= effective flange width corresponding to the flange subject to flexural compression within the unbraced length under consideration (in.) (D6.6.3)
b_{fi}	= clear width of the box flange under consideration between the webs (in.); total inside width between the plate elements providing lateral restraint to the longitudinal edges of the flange plate element under consideration (in.); inside width of the box section flange; for welded box sections, the clear width of the flange under consideration between the webs. For HSS, the provisions of Article 6.12.1.2.4 apply (in.) (6.11.2.2) (6.11.3.2) (6.12.2.2.2b)
b_{fo}	= outside width of the box section taken as the distance from the outside to the outside of the box-section webs (in.) (6.12.2.2.2b)
$b_{f,small}$	= flange width at the smallest cross-section within the unbraced length under consideration (in.) (D6.6.3)
b_{ft}	= width of the tension flange (in.); width of a box flange in tension between webs (in.); width of the tension flange, including corners and flange extensions (in.) (6.10.9.3.2) (6.11.9) (C6.12.2.2.2c)
$b_{ft\ eff}$	= effective flange width corresponding to the flange subject to flexural tension within the unbraced length under consideration (in.) (D6.6.3)
$b_{f,2}$	= flange width at the second smallest cross-section within the unbraced length under consideration (in.) (D6.6.3)
b_ℓ	= length of the longer leg of an unequal-leg angle (in.); projecting width of a longitudinal stiffener (in.) (6.9.4.4) (6.10.11.1.3)
b_m	= gross width of each plate of a box-section member taken between the mid-thickness of the adjacent plates (in.) (6.12.2.2.2e)
b_s	= width of a connection plate or projecting leg size of an end angle for a connection plate or end angle on only one side of the web, or total combined width of the connection plates or projecting leg sizes of the end angles for connection plates or end angles on both sides of the web (in.); length of the shorter leg of an unequal-leg angle (in.); effective width of the concrete deck (in.) (6.7.4.2.2) (6.9.4.4) (6.10.1.10.2)
b_{sp}	= total inside width between the plate elements providing lateral restraint to the longitudinal edges of a longitudinally stiffened plate (in.) (E6.1.3)
b_t	= projecting width of a transverse stiffener (in.); width of the projecting plate stiffener element (in.); full width of the tension flange (in.) (6.10.11.1.2) (6.10.11.2.2) (D6.1)
b_{tfs}	= smallest top-flange width within the unspliced individual girder field section under consideration (in.) (C6.10.2.2)
C	= ratio of the shear-buckling resistance to the shear yield strength determined by Eqs. 6.10.9.3.2-4, 6.10.9.3.2-5, or 6.10.9.3.2-6, as applicable, using the appropriate shear-buckling coefficient; torsional constant for noncomposite circular tubes and round HSS (in. ³) (6.10.9.2) (6.12.1.2.3b)
C_a	= smallest distance from center of stud to the edge of the concrete (in.) (6.16.4.3)
C_b	= moment-gradient modifier within the critical unbraced beam or girder segment under consideration determined as specified in Articles 6.10.8.2.3b, 6.10.8.2.3c, A6.3.3.2, or A6.3.3.3, as applicable; for Eq. 6.10.1.6-2, moment-gradient modifier calculated as specified in Article 6.10.8.2.3b or 6.10.8.2.3c, as applicable. For Eq. 6.10.1.6-3, moment-gradient modifier calculated as specified in Article A6.3.3.2 or A6.3.3.3, as applicable; moment-gradient modifier, calculated as specified in Article 6.10.8.2.3b or

- 6.10.8.2.3c, as applicable; moment-gradient modifier, calculated as specified in Article A6.3.3.2 or A6.3.3.3, as applicable within the critical unbraced beam or girder segment under consideration; moment-gradient modifier (6.7.4.2.2) (6.10.1.6) (6.10.8.2.3a) (A6.3.3.1)
- C_{be} = moment-gradient modifier for elastic lateral-torsional buckling (D6.6.2)
- C_{bs} = system moment-gradient modifier for the elastic global LTB resistance of a span acting as a system (6.10.3.4.2)
- $CFST$ = concrete-filled steel tube (6.4.1)
- C_T = factor for elastic lateral distortional buckling taken equal to 1.2 for top-flange loading (CA6.3.3.2)
- C_w = warping torsional constant (in.⁶) (6.9.4.1.3)
- C_1, C_2, C_3 = composite column constants specified in Table 6.9.5.1-1 (6.9.5.1)
- c = distance from the centroid of the section at the brace point under consideration to the centroid of the compression flange (in.); distance from the centroid of the noncomposite steel section under consideration to the centroid of the compression flange (in.); distance from the neutral axis of the effective cross-section to the extreme fiber of the compression flange (in.); distance from the center of the longitudinal reinforcement to the nearest face of a concrete-encased shape in the plane of bending (in.); one-half the chord length for a given stress state in a composite concrete-filled steel tube (in.); largest distance from the neutral axis to the extreme fiber of the transverse stiffener considered in the calculation of I_t (in.) (6.7.4.2.2) (6.10.3.4.2) (C6.12.2.2.2c) (6.12.2.3.1) (C6.12.2.3.3) (E6.1.5.2)
- c_b = one-half the chord length for a given stress state of a fictional tube modeling the internal reinforcement in a composite concrete-filled steel tube (in.) (C6.12.2.3.3)
- c_c = distance from the neutral axis of the effective cross-section to the mid-thickness of the rectangular portion of the compression flange area, considering the effective width of the slender flange and using the gross cross-section for the web (in.) (C6.12.2.2.2c)
- c_1 = effective width imperfection adjustment factor, determined from Table 6.9.4.2.2b-1 (6.9.4.2.2b)
- c_2 = effective width imperfection adjustment factor, determined from Table 6.9.4.2.2b-1 (6.9.4.2.2b)
- c_3 = effective width imperfection adjustment factor, determined from Table 6.9.4.2.2b-1 (6.9.4.2.2b)
- c_{rb} = distance from the top of the concrete deck to the centerline of the bottom layer of longitudinal concrete deck reinforcement (in.) (D6.1)
- c_{rt} = distance from the top of the concrete deck to the centerline of the top layer of longitudinal concrete deck reinforcement (in.) (D6.1)
- c_{rw} = edge-condition coefficient (6.10.1.10.2)
- D = web depth (in.); diameter of a pin (in.); outside diameter of a circular tube or round HSS (in.); total inside width between the plate elements providing lateral restraint to the longitudinal edges of the web plate element under consideration (in.); outside diameter of the steel tube in a composite concrete-filled steel tube (in.); depth of the web plate measured along the slope (in.); outside diameter of the steel tube (in.); for welded box sections, the clear distance between the flanges. For HSS, the provisions of Article 6.12.1.2.4 apply (in.); outside diameter of the tube (in.); web depth of an arch rib (in.) (6.7.4.2.2) (6.7.6.2.1) (6.9.4.2.2c) (6.9.4.5) (6.9.6.2) (6.11.9) (6.12.1.2.3b) (6.12.2.2.2b) (6.12.2.2.3) (6.14.4.2)
- D' = depth at which a composite section reaches its theoretical plastic moment capacity when the maximum strain in the concrete deck is at its theoretical crushing strain (in.) (C6.10.7.3)
- D_c = depth of the web in compression in the elastic range (in.) (6.10.1.9.1)
- $DC1$ = permanent load acting on the noncomposite section (C6.10.11.3.1)
- $DC2$ = permanent load acting on the long-term composite section (C6.10.11.3.1)
- D_{ce} = depth of the web in compression using the effective cross-section (in.); depth of the web in compression in the elastic range, considering early nominal yielding in tension when $S_{ste} < S_{sce}$, and using the effective noncomposite box cross-section based on the effective width of the compression flange, b_e , calculated as specified in Article 6.9.4.2.2 with F_{cr} taken equal to F_{yc} , and including the width of corner areas and flange extensions. For welded sections, depth from the inside of the compression flange. For HSS, the provisions of Article 6.12.1.2.4 apply (in.) (6.11.8.2.3) (6.12.2.2.2c)
- $D_{c\ eff}$ = depth of the web in compression in the elastic range for the effective cross-section within the unbraced length under consideration (in.) (D6.6.3)
- D_{cp} = depth of the web in compression at the plastic moment (in.) (6.10.6.2.2)
- D_{cpe} = depth of the web in compression at the plastic moment determined using the effective box cross-section based on the effective width of the compression flange. For welded sections, depth from the inside of the compression flange. For HSS, the provisions of Article 6.12.1.2.4 apply (in.) (6.12.2.2.2c)
- D_{eff} = effective web depth within the unbraced length under consideration (in.) (D6.6.3)
- D_n = larger of the distances from the elastic neutral axis of the cross-section to the inside face of either flange in a hybrid section, or the distance from the neutral axis to the inside face of the flange on the side of the

	neutral axis where yielding occurs first when the neutral axis is at the mid-depth of the web (in.) (6.10.1.10.1)
D_p	= distance from the top of the concrete deck to the neutral axis of the composite section at the plastic moment (in.) (6.10.7.1.2)
D_{small}	= smallest web depth within the unbraced length under consideration (in.) (D6.6.3)
D_t	= total depth of the composite section (in.) (6.10.7.1.2)
D_{taper}	= effective web depth for a variable web depth extending over all or a portion of the unbraced length under consideration (in.) (D6.6.3)
DW	= wearing surface load (C6.10.11.3.1)
D_2	= largest web depth within the unbraced length under consideration (in.) (D6.6.3)
d	= full nominal depth of the section (in.); section depth (in.); total depth of the steel section (in.); depth of the tee or width of the double-angle web leg subject to tension or compression, as applicable (in.); depth of the tee or double-angle web legs, as applicable (in.); depth of the rectangular bar (in.); depth of the member in the plane of flexure (in.); depth of the member in the plane of shear (in.); nominal diameter of a bolt (in.) (6.8.2.2) (C6.10.8.2.3b) (6.10.12.1) (6.12.2.2.4c) (6.12.2.2.4e) (6.12.2.2.7) (6.12.2.3.1) (6.12.3.1) (6.13.2.4.2)
d_b	= depth of a beam in a rigid frame (in.) (6.13.7.2)
d_c	= depth of a column in a rigid frame (in.); distance from the plastic neutral axis to the mid-thickness of the compression flange used to compute the plastic moment (in.) (6.13.7.2) (D6.1)
d_{ce}	= distance from the extreme fiber of the compression flange to the neutral axis of the effective section of a noncomposite box section (in.) (C6.12.2.2.2c)
d_{fs}	= web depth for ribs with webs that are longitudinally unstiffened; maximum distance between the compression or the tension flange and the adjacent longitudinal stiffener for ribs with webs that are longitudinally stiffened (in.) (6.14.4.2)
d_h	= depth of haunch (in.) (6.16.4.3)
d_o	= transverse stiffener spacing (in.); the smaller of the adjacent web panel widths (in.) (6.10.9.3.2) (6.10.11.1.3)
d_{rb}	= distance from the plastic neutral axis to the centerline of the bottom layer of longitudinal concrete deck reinforcement used to compute the plastic moment (in.) (D6.1)
d_{rt}	= distance from the plastic neutral axis to the centerline of the top layer of longitudinal concrete deck reinforcement used to compute the plastic moment (in.) (D6.1)
d_s	= distance from the centerline of the closest plate longitudinal stiffener or from the gauge line of the closest angle longitudinal stiffener to the inner surface or leg of the compression flange element (in.); distance from the plastic neutral axis to the mid-thickness of the concrete deck used to compute the plastic moment (in.) (6.10.1.9.2) (D6.1)
d_{smax}	= maximum shift in the shear center of the steel cross-section due to the step in the cross-section geometry at any position along the unbraced length, or at any combination of steps that are less than $0.25L_b$ from one another (in.) (D6.6.2.2)
d_t	= distance from the plastic neutral axis to the mid-thickness of the tension flange used to compute the plastic moment (in.) (D6.1)
d_w	= distance from the plastic neutral axis to the mid-depth of the web used to compute the plastic moment (in.) (D6.1)
E	= modulus of elasticity of steel (ksi); elastic modulus of the steel tube in a composite concrete-filled steel tube (ksi); elastic modulus of the internal steel reinforcement in a composite concrete-filled steel tube (ksi) (6.9.4.1.2) (6.9.6.2) (6.9.6.3.2)
E_c	= elastic modulus of the concrete in a composite concrete-filled steel tube (ksi); modulus of elasticity of concrete, determined as specified in Article 5.4.2.4 (ksi) (6.9.6.3.2) (6.10.1.1.1b)
E_e	= modified modulus of elasticity of steel for a composite column (ksi) (6.9.5.1)
EI_{eff}	= effective composite flexural cross-sectional stiffness of a composite concrete-filled steel tube (kip-in ²) (6.9.6.3.2)
EI_x, EI_y	= flexural rigidities about the x - and y -axes, respectively (kip-in ²) (C6.9.4.1.2)
EXX	= classification number for weld metal (C6.13.3.2.1)
e	= the clear spacing between adjacent ribs, centerline rib plate to centerline rib plate (in.); vertical distance to the shear center of the steel cross-section measured from the center of the compression flange (in.) (6.14.3.2.3) (CD6.6.2.2)
e_p	= distance between the centroid of the cross-section and the resultant force perpendicular to the spliced plane in gusset plates (in.) (6.14.2.8.6)
F	= thickness of a direct tension indicator (DTI) (in.); force (kip) (C6.13.2.7) (6.16.4.2)

FC	=	fracture control (C6.6.2.1)
F_{cr}	=	nominal compressive resistance of the member calculated from Eq. 6.9.4.2.2a-2 (ksi); flexural shear buckling resistance for noncomposite circular tubes and round HSS (ksi); elastic local buckling stress (ksi); critical stress (ksi); stress in the spliced section at the limit of usable resistance (ksi) (6.9.4.2.2b) (6.12.1.2.3b) (6.12.2.2.3) (6.12.2.2.4e) (6.14.2.8.6)
F_{crs}	=	local buckling stress for the stiffener (ksi) (6.10.11.1.3)
F_{crw}	=	nominal web bend-buckling resistance (ksi); nominal bend-buckling resistance for webs with longitudinal stiffeners determined as specified in Article 6.10.1.9.2 (ksi) (6.10.1.9.1) (6.10.8.2.3a)
F_{cv}	=	nominal shear resistance of the cross-section element under consideration, under shear alone, calculated as specified in Article 6.9.2.2.2 (ksi); for noncomposite rectangular box-section members, including square and rectangular HSS, and for webs of I- and H-section members, the nominal shear resistance of the cross-section element under consideration, under shear alone, and for noncomposite circular tubes and round HSS, the flexural shear or the torsional shear resistance specified in Article 6.12.1.2.3b, as applicable, or where consideration of additive torsional and flexural shear stresses is required, the torsional shear resistance specified in Article 6.12.1.2.3b (ksi); nominal shear buckling resistance of the flange subjected to shear alone (ksi); torsional shear buckling resistance for circular tubes and round HSS (ksi) (6.7.4.4.3) (6.9.2.2.2) (6.11.3.2) (6.12.1.2.3b)
F_{cvs}, F_{cwy}	=	nominal shear resistance of a cross-section element parallel to the x-axis, taken as F_{cv} for that element determined as specified in Article 6.9.2.2.2; nominal shear resistance of a cross-section element parallel to the y-axis, taken as F_{cv} for that element determined as specified in Article 6.9.2.2.2 (ksi) (6.9.2.2.2)
F_e	=	modified yield stress for a composite column (ksi); for Eq. 6.10.1.6-4, elastic LTB stress for the flange under consideration determined from Eq. 6.10.8.2.3b-2 or Eq. 6.10.8.2.3c-2, as applicable. For Eq. 6.10.1.6-5, elastic LTB stress for the flange under consideration determined from Eq. A6.3.3.2-1 or A6.3.3.3-2, as applicable (ksi); elastic LTB stress, calculated as specified in Article 6.10.8.2.3b or 6.10.8.2.3c, as applicable (ksi); elastic LTB stress, calculated as specified in Article A6.3.3.2 or A6.3.3.3, as applicable (ksi); elastic LTB stress given by Eq. A6.3.3.2-1 (ksi) (6.9.5.1) (6.10.1.6) (6.10.8.2.3a) (A6.3.3.1) (CA6.3.3.2)
$F_{e\text{ eff}}$	=	elastic LTB stress for the prismatic unbraced length with the effective cross-section (ksi) (D6.6.3)
F_{el}	=	elastic local buckling stress (ksi) (6.9.4.2.2b)
$F_{e\text{ LDB}}$	=	elastic lateral distortional buckling stress of the bottom compression flange of a composite unbraced length (ksi) (CA6.3.3.2)
F_{exx}	=	classification strength of weld metal (ksi) (C6.13.3.2.1)
F_{e1}	=	elastic LTB stress corresponding to the flange subjected to flexural compression due to M_u at the section under consideration, and with C_b taken equal to 1.0, calculated from Eq. 6.10.8.2.3b-2 or Eq. A6.3.3.2-1 as applicable; if the web of the member is slender at any cross-section of the unbraced length, including the end cross-sections, Eq. 6.10.8.2.3b-2 is to apply (ksi) (D6.6.2)
F_{fat}	=	radial fatigue shear range per unit length, taken as the larger of either F_{fat1} or F_{fat2} (kip/in.) (6.10.10.1.2)
F_{fat1}	=	radial fatigue shear range per unit length due to the effect of any curvature between brace points (kip/in.) (6.10.10.1.2)
F_{fat2}	=	radial fatigue shear range per unit length due to torsion caused by effects other than curvature, such as skew (kip/in.) (6.10.10.1.2)
F_ℓ	=	statically equivalent uniformly distributed lateral force due to the factored loads from concrete deck overhang brackets (kip/in.) (C6.10.3.4.1)
FLB	=	flange local buckling (C6.10.8.2.1)
F_{max}	=	maximum potential compression flange flexural resistance (ksi) (C6.10.8.2.1)
F_n	=	average stress on the gross area of a welded plate supported along two longitudinal edges (ksi); nominal flexural resistance of a flange (ksi) (C6.9.4.2.2b) (C6.10.8.2.3)
F_{nc}	=	nominal flexural resistance of a compression flange (ksi) (6.9.2.2.1)
$F_{nc(FLB)}$	=	nominal compression FLB flexural resistance (ksi) (CD6.4.1)
F_{nt}	=	nominal flexural resistance of a tension flange (ksi); nominal flexural resistance based on tension flange yielding (ksi) (6.9.2.2.1) (6.11.8.1.2)
F_p	=	total radial force in the concrete deck at the point of maximum positive live load plus impact moment for the design of the shear connectors at the strength limit state, taken equal to zero for straight spans or segments (kip) (6.10.10.4.2)
F_{px}	=	transverse seismic shear force on the deck within the span under consideration (6.16.4.2)
F_{rc}	=	net range of cross-frame force at the top flange (kip) (6.10.10.1.2)

- F_T = total radial force in the concrete deck between the point of maximum positive live load plus impact moment and the centerline of an adjacent interior support for the design of shear connectors at the strength limit state, taken equal to zero for straight spans or segments (kip) (6.10.10.4.2)
- F_u = minimum tensile strength of steel (ksi); specified minimum tensile strength of the tension flange determined as specified in Table 6.4.1-1 (ksi); specified minimum tensile strength of a stud shear connector (ksi); specified minimum tensile strength of a connected part (ksi); tensile strength of a connected element (ksi); specified minimum tensile strength of a gusset plate (ksi) (6.4.1) (6.8.2.3.3) (6.10.10.4.3) (6.13.2.9) (6.13.5.3) (6.14.2.8.6)
- F_{ub} = specified minimum tensile strength of a bolt (ksi) (6.13.2.7)
- F_{vr} = factored torsional shear resistance of a box flange (ksi) (6.11.1.1)
- F_y = specified minimum yield strength of a pin (ksi); specified minimum yield strength of a pin plate (ksi); specified minimum yield strength of the eyebar (ksi); specified minimum yield strength of a plate element or longitudinally stiffened plate panel (ksi); specified minimum yield strength of a connected material (ksi); specified minimum yield strength of a gusset plate (ksi); specified minimum yield strength of steel (ksi); specified minimum yield strength of a longitudinally stiffened plate element (ksi); smallest specified minimum yield strength of a stiffened plate and transverse stiffener (ksi) (6.7.6.2.1) (6.7.6.3) (6.8.7.2) (6.9.4.5) (6.9.5.1) (6.13.4) (6.14.2.8.3) (E6.1.4) (E6.1.5.2)
- F_{yb} = specified minimum yield strength of the internal steel reinforcement in a composite concrete-filled steel tube (ksi) (6.9.6.3.2)
- F_{yc} = specified minimum yield strength of the compression flange (ksi); specified minimum yield strength of the compression flange at the cross-section where $f_{bu}/R_b R_h F_{yc}$ is maximum in the unbraced length under consideration, including the end cross-sections (ksi); specified minimum yield strength of the longitudinally stiffened compression flange (ksi) (6.9.2.2.1) (6.10.1.6) (6.11.8.2.3)
- F_{yf} = specified minimum yield strength of a flange (ksi); specified minimum yield strength of the flange under consideration (ksi) (C6.10.1.3) (6.14.4.2)
- F_{yr} = specified minimum yield strength of the longitudinal reinforcement (ksi); compression-flange stress at the onset of nominal yielding within the cross-section, including residual stress effects but not including compression-flange lateral bending, taken as the smaller of $0.7F_{yc}$ and F_{yws} , but not less than $0.5F_{yc}$ (ksi); compression flange stress at the onset of nominal yielding including residual stress and geometric imperfection effects, but not including compression flange lateral bending, taken as $0.5F_{yc}$ for members with longitudinally unstiffened webs. For members with longitudinally stiffened webs, F_{yr} shall be taken as the smaller of $0.5F_{yc}$ and F_{crw} (ksi); compression flange stress at the onset of nominal yielding, including residual stress and geometric imperfection effects, but not including compression flange lateral bending, taken as $0.5F_{yc}$ for welded sections, and as $0.7F_{yc}$ for rolled sections (ksi) (6.9.5.1) (6.10.8.2.2) (6.10.8.2.3a) (A6.3.3.1)
- F_{yrb} = specified minimum yield strength of the bottom layer of longitudinal concrete deck reinforcement (ksi) (D6.1)
- F_{yrs} = specified minimum yield strength of the longitudinal concrete deck reinforcement (ksi) (D6.3.2)
- F_{yrt} = specified minimum yield strength of the top layer of longitudinal concrete deck reinforcement (ksi) (D6.1)
- F_{ys} = specified minimum yield strength of a stiffener (ksi) (6.10.11.1.3)
- F_{ysp} = specified minimum yield strength of a longitudinally stiffened plate (ksi) (E6.1.2)
- F_{yst} = specified minimum yield strength of the steel tube in a composite concrete-filled steel tube (ksi) (6.9.6.2)
- F_{yt} = specified minimum yield strength of a tension flange (ksi) (6.9.2.2.1)
- F_{yw} = specified minimum yield strength of the web (ksi) (6.10.11.1.3)
- f = shear flow in a box section (kip/in.) (C6.11.1.1)
- f_1 = smaller longitudinal stress at the longitudinal edges of the plate element or longitudinally stiffened plate panel at the cross-section under consideration, taken as positive in compression and negative in tension (ksi) (6.9.4.5)
- f_2 = larger longitudinal compressive stress at the longitudinal edges of the plate element or longitudinally stiffened plate panel at the cross-section under consideration, taken as positive (ksi) (6.9.4.5)
- f_a = factored longitudinal stress in a longitudinal stiffener due to axial compression and flexure (ksi) (CE6.1.4)
- f_{bu} = for unbraced lengths where Article 6.10.8.2.3 is applied, value of the flange compressive stress at the cross-section where $f_{bu}/R_b R_h F_{yc}$ is maximum in the unbraced length under consideration, including the end cross-sections, calculated without consideration of flange lateral bending (ksi); factored flange compressive stress at the cross-section under consideration, calculated without consideration of flange lateral bending (ksi); factored longitudinal stress in the compression flange of the gross cross-section calculated without consideration of longitudinal warping (ksi). The box-flange area of the gross cross-section shall be reduced, if applicable, to account for shear lag as specified in Article 6.11.1.1 in the

calculation of the stress; total factored longitudinal stress in the compression or tension flange of the gross cross-section calculated without consideration of flange lateral bending or longitudinal warping, as applicable (ksi). The box-flange area of the gross cross-section shall be reduced, if applicable, to account for shear lag as specified in Article 6.11.1.1 in the calculation of the stress (6.10.1.6) (6.10.8.2.3a) (6.11.3.2) (6.11.7.2.1)

- f_{by} = total factored stress in the compression flange of the gross cross-section of a box girder at an interior pier caused by major-axis bending of the internal diaphragm over the bearing sole plate (ksi) (C6.11.8.1.1)
- f_c = maximum longitudinal compressive stress acting on the gross cross-section in the plate element or longitudinally stiffened plate panel under consideration at the service limit state and for constructibility (ksi); compression-flange stress due to the Service II loads calculated without consideration of flange lateral bending (ksi); sum of the various compression flange flexural stresses caused by the different loads, i.e., $DC1$, $DC2$, DW , and $LL+IM$, acting on their respective sections (ksi) (6.9.4.5) (6.10.4.2.2) (D6.3.1)
- f'_c = specified minimum 28-day compressive strength of concrete (ksi); specified minimum 28-day compressive strength of the concrete in a composite concrete-filled steel tube (ksi) (6.9.5.1) (6.9.6.3.2)
- f_d = total factored shear stress in the compression flange of the gross cross-section of a box girder at an interior pier caused by the internal diaphragm vertical shear (ksi) (C6.11.8.1.1)
- f_{DC1} = compression-flange stress caused by the factored permanent load applied before the concrete deck has hardened or is made composite, calculated without consideration of flange lateral bending (ksi) (6.10.1.10.2)
- f_{DC2} = compression-flange stress caused by the factored permanent load acting on the long-term composite section, calculated without consideration of flange lateral bending (ksi) (C6.10.11.3.1)
- f_f = flange stress due to the Service II loads calculated without consideration of flange lateral bending (ksi) (6.10.4.2.2)
- f_ℓ = flange lateral bending stress (ksi); flange lateral bending stress due to the Service II loads (ksi); lateral bending stress in the flange under consideration at an interior-pier section (ksi) (6.10.1.6) (6.10.4.2.2) (B6.4.2.1)
- $f_{\ell 1}$ = first-order compression flange lateral bending stress at a section, or the maximum first-order lateral bending stress in the compression flange throughout the unbraced length, as applicable (ksi) (6.10.1.6)
- f_{LL+IM} = compression-flange stress caused by the factored vehicular live load plus impact acting on the short-term composite section, calculated without consideration of flange lateral bending (ksi) (C6.10.11.3.1)
- f_n = normal stress in the inclined bottom flange of a variable web depth member (ksi); largest of the specified minimum yield strengths of each component included in the calculation of A_m for a hybrid section when yielding occurs first in one of the components, or the largest of the elastic stresses in each component on the side of the neutral axis corresponding to D_n at first yield on the opposite side of the neutral axis (ksi) (C6.10.1.4) (6.10.1.10.1)
- f_r = modulus of rupture of concrete (ksi) (6.10.1.7)
- f_s = flexural stress due to the factored loads in a longitudinal web stiffener (ksi) (6.10.11.3.1)
- f_{sr} = stress range in the longitudinal reinforcement at the interior pier under the applicable fatigue load combination (ksi) (6.10.10.3)
- f_t = stress due to the factored loads on the gross area of a tension flange calculated without consideration of flange lateral bending (ksi); sum of the various tension-flange flexural stresses caused by the different loads, i.e., $DC1$, $DC2$, DW , and $LL+IM$, acting on their respective sections (ksi) (6.10.1.8) (D6.3.1)
- f_v = factored St. Venant torsional shear stress in the flange at the section under consideration (ksi); total factored St. Venant torsional shear stress in the compression or tension flange, as applicable, at the section under consideration (ksi); total factored St. Venant torsional shear stress on the gross cross-sectional area of the compression flange (ksi) (6.11.3.2) (6.11.7.2.2) (C6.11.8.1.1)
- f_{ve} = factored shear stress due to torsion in the cross-section element under consideration (ksi); total factored shear stress due to torsion and/or flexure, as applicable, calculated in a cross-section element oriented parallel to the x - or y -axis of the cross-section used in calculating the reduction factor, Δ , applied to the factored axial resistance to account for the effect of torsional and/or flexural shear in a noncomposite box-section member, circular tube, or an I- or H-section member (ksi); total factored resultant shear stress due to flexure and/or shear stress due to torsion within the wall of a noncomposite circular tube (ksi) (6.7.4.4.3) (6.9.2.2.2) (C6.9.2.2.2)
- f_{vex} = total factored shear stress due to torsion and/or flexure, as applicable, calculated in a cross-section element oriented parallel to the x -axis of the cross-section (ksi) (6.9.2.2.2)
- f_{vey} = total factored shear stress due to torsion and/or flexure, as applicable, calculated in a cross-section element oriented parallel to the y -axis of the cross-section (ksi); factored flexural shear stress in the web of an I- or H-section member (ksi) (6.9.2.2.2) (C6.9.2.2.2)

f_{vex1}, f_{vex2}	= factored flexural shear stresses parallel to the x -axis within the component plates of a noncomposite box-section member, or in the flanges of an I- or H-section member (ksi) (C6.9.2.2.2)
f_{vey1}, f_{vey2}	= factored flexural shear stresses parallel to the y -axis within the component plates of a noncomposite box-section member (ksi) (C6.9.2.2.2)
f_{xx}	= various compression flange flexural stresses caused by the different factored loads, i.e., $DC1$, $DC2$, DW , and $LL+IM$, acting on their respective sections (ksi) (C6.10.11.3.1)
G	= shear modulus of elasticity for steel = $0.385E$ (ksi) (6.9.4.1.3)
GJ	= St. Venant torsional rigidity (kip-in ²) (C6.9.4.1.3)
g	= gauge of the same two holes (in.); gauge between bolts (in.) (6.8.3) (6.13.2.6.2)
H	= overall height of rectangular HSS member, measured in the plane of the connection (in.) (6.8.2.2)
H_w	= horizontal force in the web at a point of splice (kip) (C6.13.6.1.3c)
HPS	= high-performance steel (C6.4.1)
h	= distance between flange centroids (in.); distance between centroids of individual component shapes perpendicular to the member axis of buckling (in.) (C6.9.4.1.3) (6.9.4.3.1)
h_b	= height of a cross-frame measured between the centroids of the top and bottom struts, or depth of a diaphragm, as applicable (in.) (6.7.4.2.2)
h_{eff}	= effective embedment depth of a stud shear connector (in.); depth between the centerline of the flanges of the effective cross-section (in.) (6.16.4.3) (D6.6.3)
h_h	= effective height of the stud above the top of the haunch to the underside of the head (in.) (6.16.4.3)
h_i	= respective distances along the web from the top and bottom of a cross-frame or diaphragm member, connection plate, or end angle, as applicable, to the adjacent flange (in.) (6.7.4.2.2)
h_o	= distance between the flange centroids of the girder section at the brace point under consideration (in.); distance between flange centroids (in.) (6.7.4.2.2) (6.12.2.2.5)
I	= moment of inertia of the short-term composite section, or optionally in regions of negative flexure of straight girders only, the moment of inertia of the steel section plus the longitudinal reinforcement if the concrete is not considered to be effective in tension in computing the range of longitudinal stress (in. ⁴); moment of inertia of the effective internal interior-pier diaphragm within a box section (in. ⁴) (6.10.10.1.2) (C6.11.8.1.1)
I_b	= moment of inertia of the diaphragm member about the horizontal centroidal axis of the section (in. ⁴) (6.7.4.2.2)
I_c	= uncracked moment of inertia of the concrete in a composite concrete-filled steel tube about the centroidal axis (in. ⁴) (6.9.6.3.2)
I_{eff}	= effective noncomposite moment of inertia about the vertical centroidal axis of a single girder within the span under consideration used in calculating the elastic global LTB resistance of the span (in. ⁴); effective moment of inertia about the vertical centroidal axis of the girder (in. ⁴) (6.10.3.4.2) (CA6.3.3.2)
I_t	= moment of inertia of a longitudinal web stiffener including an effective width of web taken about the neutral axis of the combined section (in. ⁴) (6.10.11.1.3)
I_p	= lateral moment of inertia of a unit width of a longitudinally stiffened plate (in. ³) (E6.1.3)
I_{ps}	= polar moment of inertia of a longitudinal stiffener alone about the attached edge (in. ⁴) (E6.1.4)
IRM	= internally redundant member (6.6.2.2)
I_s	= moment of inertia of a single flange longitudinal stiffener taken about an axis parallel to a box flange and taken at the base of the stiffener (in. ⁴); moment of inertia of an individual stiffener strut composed of the stiffener plus the tributary width of the longitudinally stiffened plate under consideration, taken about an axis parallel to the face of the longitudinally stiffened plate and passing through the centroid of the gross combined area of the longitudinal stiffener and its tributary plate width (in. ⁴) (6.11.8.2.3) (E6.1.3)
I_{si}	= moment of inertia of the internal steel reinforcement in a composite concrete-filled steel tube about the centroidal axis (in. ⁴) (6.9.6.3.2)
I_{st}	= moment of inertia of the steel tube in a composite concrete-filled steel tube about the centroidal axis (in. ⁴) (6.9.6.3.2)
I_t	= moment of inertia of a web transverse stiffener taken about the edge in contact with the web for single stiffeners and about the mid-thickness of the web for stiffener pairs (in. ⁴); moment of inertia of a transverse stiffener, including a width of the stiffened plate equal to $9t_{sp}$, but not more than the actual dimension available, on each side of the stiffener avoiding any overlap with contributing parts to adjacent stiffeners or diaphragms, taken about the centroidal axis of the combined section (in. ⁴) (6.10.11.1.3) (E6.1.5.2)
I_{t1}	= minimum moment of inertia of the transverse stiffener required for the development of the web shear buckling resistance (in. ⁴) (6.10.11.1.3)
I_{t2}	= minimum moment of inertia of the transverse stiffener required for the development of the full web shear buckling plus post-buckling tension-field action resistance (in. ⁴) (6.10.11.1.3)

I_x	= noncomposite girder moment of inertia about the horizontal centroidal axis of the section at the brace point under consideration (in. ⁴); moments of inertia about the major principal axis of the cross-section (in. ⁴); noncomposite moment of inertia about the horizontal centroidal axis of a single girder within the span under consideration (in. ⁴) (6.7.4.2.2) (6.9.4.1.3) (6.10.3.4.2)
I_{xe}	= effective moment inertia of the cross-section about the axis of bending (in. ⁴) (6.12.2.2.2c)
I_y	= noncomposite girder moment of inertia about the vertical centroidal axis of the section at the brace point under consideration (in. ⁴); moments of inertia about the minor principal axis of the cross-section (in. ⁴); noncomposite moment of inertia about the vertical centroidal axis of a single girder within the span under consideration (in. ⁴); moment of inertia about the y-axis (in. ⁴) (6.7.4.2.2) (6.9.4.1.3) (6.10.3.4.2) (6.12.2.2.4c)
I_{yb1}	= lateral moment of inertia of the bottom flange of the steel section located closer to the brace point with the smaller magnitude of moment, taken about the vertical axis in the plane of the web (in. ⁴) (6.10.8.2.3c)
I_{yb2}	= lateral moment of inertia of the bottom flange of the steel section located closer to the brace point with the larger magnitude of moment, taken about the vertical axis in the plane of the web (in. ⁴) (6.10.8.2.3c)
I_{yc}	= moment of inertia of the girder compression flange about the vertical centroidal axis of the section at the brace point under consideration (in. ⁴); moment of inertia of the compression flange of a steel section about the vertical axis in the plane of the web (in. ⁴); moment of inertia of the compression flange about the vertical centroidal axis of a single girder within the span under consideration (in. ⁴) (6.7.4.2.2) (6.10.2.2) (6.10.3.4.2)
I_{yeff}	= effective out-of-plane moment of inertia of a girder (in. ⁴) (6.7.4.2.2)
I_{yP}	= lateral moment of inertia of the flange opposite to the one that follows the variation in the web depth, taken about a vertical axis in the plane of the web (in. ⁴) (D6.6.2.1)
I_{yt}	= moment of inertia of the girder tension flange about the vertical centroidal axis of the section at the brace point under consideration (in. ⁴); moment of inertia of the tension flange of a steel section about the vertical axis in the plane of the web (in. ⁴); moment of inertia of the tension flange about the vertical centroidal axis of a single girder within the span under consideration (in. ⁴) (6.7.4.2.2) (6.10.2.2) (6.10.3.4.2)
I_{yt1}	= lateral moment of inertia of the top flange of the steel section located closer to the brace point with the smaller magnitude of moment, taken about the vertical axis in the plane of the web (in. ⁴) (6.10.8.2.3c)
I_{yt2}	= lateral moment of inertia of the top flange of the steel section located closer to the brace point with the larger magnitude of moment, taken about the vertical axis in the plane of the web (in. ⁴) (6.10.8.2.3c)
I_{yTop}	= moment inertia of the top flange about the vertical centroidal axis (in. ⁴) (C6.10.8.2.3b)
I_{yV}	= lateral moment of inertia of the flange that follows the variation in web depth, taken about an axis normal to the flange and in the plane of the web (in. ⁴) (D6.6.2.1)
IM	= dynamic load allowance from Article 3.6.2
J	= St. Venant torsional inertia (in. ⁴); transverse stiffener bending rigidity parameter; St. Venant torsional constant of the gross cross-section (in. ⁴); St. Venant torsional constant (in. ⁴) (C6.7.4.3) (6.10.11.1.3) (6.12.2.2.2e) (A6.3.3.1)
J_{eff}	= St. Venant torsional constant for the prismatic unbraced length with the effective cross-section (in. ⁴) (D6.6.3)
J_s	= St. Venant torsional constant of a longitudinal stiffener alone, not including the contribution from the stiffened plate (in. ⁴) (E6.1.4)
K	= effective length factor; effective length factor in the plane of buckling determined as specified in Article 4.6.2.5; effective length factor as specified in Article 4.6.2.5; effective column length factor taken as 0.50 for chord splices (6.9.3) (6.9.4.1.2) (6.9.6.3.2) (6.14.2.8.6)
K_c	= creep factor taken equal to 0.80 for Class C galvanized faying surfaces or for duplex-coated faying surfaces utilizing a coating over a galvanized subsurface, and taken equal to 1.0 for all other surface conditions (6.13.2.8)
K_h	= hole size factor for bolted connections (6.13.2.8)
$K\ell$	= effective length in the plane of buckling (in.) (E6.1.1)
$(K\ell/r)_{eff}$	= effective slenderness ratio for a single-angle compression member (6.9.4.1.1)
K_s	= surface condition factor for bolted connections (6.13.2.8)
$K_x\ell_x$	= effective length for flexural buckling about the x-axis (in.) (6.9.4.1.3)
$K_y\ell_y$	= effective length for flexural buckling about the y-axis (in.) (6.9.4.1.3)
$K_z\ell_z$	= effective length for torsional buckling (in.) (6.9.4.1.3)
$K\ell/r$	= slenderness ratio (6.9.3)

k	=	plate-buckling coefficient, considering any gradient in the longitudinal stress; web bend-buckling coefficient; shear-buckling coefficient for webs; plate-buckling coefficient for uniform normal stress in box flanges; distance from the outer face of the flange to the toe of a web fillet of a rigid-frame member to be stiffened (in.); distance from the outer face of a flange resisting a concentrated load or a bearing reaction to the web toe of the fillet (in.) (6.9.4.5) (6.10.1.9.1) (6.10.9.3.2) (6.11.3.2) (6.13.7.2) (D6.5.2)
k_c	=	FLB coefficient (6.9.4.2.1)
k_s	=	shear buckling coefficient; plate-buckling coefficient for shear stress (C6.9.2.2.2) (6.11.8.2.2b)
k_{sf}	=	elastic web bend-buckling coefficient for fully restrained longitudinal edge conditions (C6.10.1.9.1)
k_{ss}	=	elastic web bend-buckling coefficient for simply supported longitudinal edge conditions (C6.10.1.9.1)
L	=	actual span length bearing to bearing along the centerline of the bridge (ft); length of the span under consideration (in.). For a cross-frame or diaphragm located at an interior support, the average length of the spans on either side of the interior support shall be used for L ; average length of the connection longitudinal welds or the out-to-out distance between the bolts in the connection parallel to the line of force (in.); length of the member (in.); distance from a single bolt to the free edge of the member measured parallel to the line of applied force (in.) (6.7.2) (6.7.4.2.2) (6.8.2.2) (6.12.1.2.3b) (C6.13.2.9)
L_B	=	minimum bolt body length (in.) (C6.13.2.7)
L_b	=	spacing of intermediate diaphragms (ft); diaphragm or cross-frame spacing (ft); unbraced length (in.); unbraced length for lateral displacement or twist, as applicable (in.) (6.7.4.2) (C6.7.4.2) (6.10.1.6) (6.12.2.2.7)
L_c	=	clear distance between bolt holes or between the bolt hole and the end of the member in the direction of the applied bearing force (in.) (6.13.2.9)
L_{cp}	=	length of a cover plate (ft) (6.10.12.1)
L_d	=	length of a cross-frame diagonal member (in.) (6.7.4.2.2)
L_{db}	=	developed unbraced length along the vertical curve of an arch rib between the brace points (in.) (6.14.4.5)
L_{eff}	=	effective span for the calculation of shear lag (in.) (6.12.2.2.2g)
L_{fs}	=	length of the unspliced individual girder field section under consideration (in.) (C6.10.2.2)
LL	=	vehicular live load
L_{mid}	=	in a gusset plate connection, the distance from the last row of fasteners in the compression member under consideration to the first row of fasteners in the closest adjacent connected member, measured along the line of action of the compressive axial force (in.) (6.14.2.8.4)
L_n	=	arc length between the point of maximum positive live load plus impact moment and the centerline of an adjacent interior support (ft) (6.10.10.4.2)
L_{NOM}	=	minimum nominal bolt length (in.) (C6.13.2.7)
L_p	=	for Eq. 6.10.1.6-2, limiting unbraced length given by Eq. 6.10.8.2.3a-4. For Eq. 6.10.1.6-3, limiting unbraced length given by Eq. A6.3.3.1-4 (in.); limiting unbraced length to achieve the nominal flexural resistance of $R_b R_h F_{yc}$ under uniform bending (in.); arc length between an end of the girder and an adjacent point of maximum positive live load plus impact moment (ft); limiting unbraced length to achieve the nominal flexural resistance $R_f R_b R_{pc} M_{yc}$ under uniform moment (in.); limiting unbraced length to achieve the nominal flexural resistance M_p under uniform bending (in.); limiting unbraced length to achieve the nominal flexural resistance $R_{pc} M_{yc}$ under uniform bending (in.) (6.10.1.6) (6.10.8.2.3a) (6.10.10.4.2) (6.12.2.2.2e) (6.12.2.2.5) (A6.3.3.1)
L_{PLY}	=	total nominal thickness of the connection plies (in.) (C6.13.2.7)
L_{PRM}	=	load path redundant member (6.6.2.1)
L_r	=	limiting unbraced length to achieve the onset of nominal yielding in either flange under uniform bending with consideration of compression flange residual stress effects (in.); limiting unbraced length to achieve the onset of nominal yielding in either flange under uniform bending considering compression flange residual stress and geometric imperfection effects (in.); limiting unbraced length for calculation of the LTB resistance (in.) (6.7.4.2.1) (6.10.8.2.3a) (6.12.2.2.2e)
$LRFD$	=	load and resistance factor design
L_{SP}	=	length to the location of the furthest shear plane measured from the bolt head (in.) (C6.13.2.7)
L_{splice}	=	in a gusset plate connection, the center-to-center distance between the first lines of fasteners in the adjoining chords at a chord splice (6.14.2.8.6)
L_T	=	bolt thread length (in.) (C6.13.2.7)
LTB	=	lateral-torsional buckling (C6.7.4.2.1)
L_v	=	distance between points of maximum and zero shear (in.) (6.12.1.2.3b)
ℓ	=	unbraced member length (in.); unbraced length in the plane of buckling (in.); distance between the work points of the joints measured along the length of the angle (in.); unbraced length of a composite concrete-filled steel tube column (in.); distance between brace points (in.); buckling length of individual stiffener

- struts, taken equal to the smaller of a and ℓ_c (in.) (6.8.4) (6.9.4.1.2) (6.9.4.4) (6.9.6.3.2) (6.10.10.1.2) (E6.1.3)
- ℓ_c = characteristic buckling length of the stiffener struts of a longitudinally stiffened plate (in.) (E6.1.3)
- M = bending moment about the major axis of the cross-section (kip-in.) (C6.10.1.4)
- M_1 = bending moment about the major axis of the cross-section at the brace point with the lower moment due to the factored loads adjacent to an interior-pier section from which moments are redistributed taken as either the maximum or minimum moment envelope value, whichever produces the smallest permissible unbraced length (kip-in.) (B6.2.4)
- M_2 = bending moment about the major axis of the cross-section at the brace point with the higher moment due to the factored loads adjacent to an interior-pier section from which moments are redistributed taken as the critical moment envelope value (kip-in.) (B6.2.4)
- M_A, M_B, M_C = absolute value of the factored major-axis bending moment at one-quarter, one-half and three-quarters of the unbraced length under consideration (points A, B, and C), respectively, calculated from the moment envelope values that produce the largest flexural compression in the flange under consideration at these points, or the smallest flexural tension in this flange if the flange is never in compression at the point. (kip-in.) (6.10.8.2.3b)
- M_{AD} = additional bending moment that must be applied to the short-term composite section to cause nominal yielding in either steel flange (kip-in.) (D6.2.2)
- M_{br} = required strength of a torsional brace (kip-in.) (6.7.4.2.2)
- $M_{br, skew}$ = required strength of a torsional brace skewed relative to a line normal to the longitudinal axis of the bridge (kip-in.) (C6.7.4.2.2)
- M_c = column moment due to the factored loading in a rigid frame (kip-in.) (6.13.7.2)
- M_{cr} = elastic LTB moment (kip-in.) (6.12.2.2.4c)
- M_{D1} = bending moment caused by the factored permanent load applied before the concrete deck has hardened or is made composite (kip-in.) (D6.2.2)
- M_{D2} = bending moment caused by the factored permanent load applied to the long-term composite section (kip-in.) (D6.2.2)
- M_e = elastic LTB moment $F_e S_{xc}$ considering the direction of bending associated with M_u (kip-in.); critical elastic moment envelope value due to the factored loads at an interior-pier section from which moments are redistributed (kip-in.) (CA6.3.3.2) (B6.3.3.1)
- M_{e1} = elastic LTB moment at the section under consideration, $F_{e1} S_{xc}$, considering the direction of bending associated with M_u (kip-in.) (D6.6.2)
- $M_{e1A}, M_{e1B}, M_{e1C}$ = elastic LTB moment at the section under consideration, $F_{e1} S_{xc}$, considering the direction of bending associated with M_u calculated at one-quarter, one-half and three-quarters of the unbraced length under consideration (points A, B, and C), respectively (kip-in.) (D6.6.2)
- M_{eLDB} = elastic lateral distortional buckling moment of a torsionally restrained member (kip-in.) (CA6.3.3.2)
- M_{gs} = elastic global LTB resistance of a span (kip-in.) (6.10.3.4.2)
- M_ℓ = lateral bending moment in the flanges due to the eccentric loadings from concrete deck overhang brackets (kip-in.) (C6.10.3.4.1)
- M_{large} = factored major-axis moment envelope value at the end of the unbraced length under consideration with the larger magnitude of moment (kip-in.). The ratio of M_{small}/M_{large} should be determined considering the sign of the moments. (C6.10.8.2.3b)
- M_{max} = maximum potential flexural resistance based on the compression flange (kip-in.); absolute value of the factored maximum major-axis moment in the unbraced length, calculated from the moment envelope value that produces the largest flexural compression in the flange under consideration (kip-in.) (C6.10.8.2.1) (6.10.8.2.3b)
- M_n = nominal flexural resistance of a section (kip-in.); nominal flexural resistance of a composite concrete-filled steel tube as a function of the nominal axial resistance, P_n (kip-in.) (6.10.7.1.1) (C6.12.2.3.3)
- M_{nc} = nominal flexural resistance based on the compression flange (kip-in.) (6.9.2.2.1)
- $M_{nc(FLB)}$ = nominal flexural resistance based on compression FLB (kip-in.) (CD6.4.2)
- M_{nt} = nominal flexural resistance based on the tension flange (kip-in.) (6.9.2.2.1)
- M_p = plastic moment (kip-in.); plastic moment = $F_y Z_x \leq 1.6 M_y$ (kip-in.) (6.10.7.1.2) (6.12.2.2.4c)
- M_{pe} = plastic moment using the effective box cross-section based on the effective width of the compression flange (kip-in.); negative-flexure effective plastic moment at interior-pier sections from which moments are redistributed (kip-in.) (6.12.2.2.2c) (B6.3.3.1)

- M_{ps} = plastic moment resistance of the steel section of a concrete-encased member (kip-in.) (6.12.2.3.1)
 M_r = factored tension rupture flexural resistance about the axis of bending under consideration (kip-in.); factored flexural resistance (kip-in.) (6.8.2.3.3) (6.12.1.2.1)
 M_{rd} = redistribution moment (kip-in.) (B6.3.3.1)
 M_{rx}, M_{ry} = factored flexural resistance about the x - and y -axes, respectively, excluding tension-flange rupture (kip-in.) (6.8.2.3.1)
 M_{rxc} = factored flexural resistance about the x -axis taken as ϕ_f times the nominal flexural resistance about the x -axis considering compression buckling, determined as specified in Article 6.10 or 6.12, as applicable (kip-in.) (6.8.2.3.1)
 M_{rxpe} = for I-section members, ϕ_f times the plastic moment about the x -axis neglecting any web longitudinal stiffeners; for noncomposite box-section members, ϕ_f times the effective plastic moment about the x -axis, based on the effective compression flange area as defined in Article 6.12.2.2.2c or 6.12.2.2.2d, as applicable, and neglecting any web longitudinal stiffeners (kip-in.) (6.8.2.3.1)
 M_{ryc} = factored flexural resistance about the y -axis taken as ϕ_f times the nominal flexural resistance about the y -axis considering compression buckling, determined as specified in Article 6.12, as applicable; $M_{ryc} = M_{ryt} = M_{ry}$ for I-section members (kip-in.) (6.8.2.3.1)
 M_{rype} = for I-section members, ϕ_f times the plastic moment about the y -axis neglecting any web longitudinal stiffeners; for noncomposite box-section members, ϕ_f times the effective plastic moment about the y -axis, based on the effective compression flange area as defined in Article 6.12.2.2.2c or 6.12.2.2.2d, as applicable, and neglecting any web longitudinal stiffeners (kip-in.) (6.8.2.3.1)
 M_{small} = factored major-axis moment envelope value at the end of the unbraced length under consideration with the smaller magnitude of moment (kip-in.). The ratio of M_{small}/M_{large} should be determined considering the sign of the moments. (C6.10.8.2.3b)
 M_u = factored major-axis bending moment for the limit-state load combination specified in Article 3.4.1 or 3.4.2.1, as applicable (kip-in.); moment due to the factored loads (kip-in.); factored moment about the axis of bending at the cross-section containing the flange bolt holes taken as positive for tension in the flange under consideration and negative for compression (kip-in.); for unbraced lengths where Article A6.3.3 is applied, value of the major axis bending moment at the cross-section where $M_u/R_{pc}M_{yc}$ is maximum in the unbraced length under consideration, including the end cross-sections (kip-in.); factored major-axis bending moment at the cross-section under consideration (kip-in.); total factored bending moment about the major axis of the gross cross-section at the section under consideration (kip-in.) (6.7.4.2.2) (6.7.6.2.1) (6.8.2.3.3) (6.10.1.6) (6.10.8.2.3b) (6.11.7.1.1)
 $M_{u\ max}$ = maximum factored major-axis bending moment within the unbraced length under consideration, including the end cross-sections, calculated from the moment envelope value that produces the largest flexural compression in the flange under consideration (kip-in.) (D6.6.3)
 $\left(\frac{M_u}{M_{el}}\right)_{\max}$ = maximum ratio of the factored major-axis bending moment to the elastic LTB moment for the unbraced length under consideration, $M_{el} = F_e S_{xc}$, with F_e determined from Eq. 6.10.8.2.3b-2 or Eq. A6.3.3.2-1 as applicable, and with C_b taken equal to 1.0; M_u is calculated from the moment envelope values that produce the largest flexural compression in the flange under consideration, and M_{el} is calculated for the direction of bending causing flexural compression in the flange under consideration; if the web of the member is slender at any cross-section of the unbraced length, including the end cross-sections, Eq. 6.10.8.2.3b-2 applies (kip-in.) (D6.6.2)
 M_{ux}, M_{uy} = factored moments about the x - and y -axes, respectively (kip-in.); factored biaxial bending moments about the x - and y -axes, respectively, applied to a noncomposite box-section member, circular tube, or an I- or H-section member (kip-in.) (6.8.2.3.1) (C6.9.2.2.2)
 M_y = yield moment (kip-in.); yield moment = $F_y S_x$ (kip-in.) (6.10.7.1.2) (6.12.2.2.4b)
 M_{yc} = yield moment with respect to the compression flange determined as specified in Article D6.2 (kip-in.); yield moment with respect to the compression flange determined as specified in Article D6.2 at the cross-section where $M_u/R_{pc}M_{yc}$ is maximum in the unbraced length under consideration, including the end cross-sections (kip-in.); yield moment with respect to the compression flange determined as specified in Article D6.2.1 or D6.2.3, as applicable, using the gross cross-section including corner areas and flange extensions (kip-in.); yield moment of the composite section determined as specified in Article D6.2 (kip-in.) (6.9.2.2.1) (6.10.1.6) (C6.11.8.1.1) (6.12.2.3.1)
 M_{yce} = yield moment with respect to the compression flange determined as specified in Article D6.2.1 or D6.2.3, as applicable, using the effective width of the compression flange, b_e , calculated as specified in Article 6.9.4.2.2b with F_{cr} taken equal to F_{yc} and including the width of the corner areas and flange extensions

- (kip-in.). The box-flange area of the gross cross-section shall not be reduced to account for shear lag in the calculation; yield moment of the effective noncomposite box section with respect to the compression flange taken as $F_{yc}S_{xce}$ for sections in which $S_{xte} \geq S_{xce}$ and calculated as the moment at nominal first yielding of the compression flange, considering early nominal yielding in tension, for sections in which $S_{xte} < S_{xce}$ (kip-in.) (C6.11.8.1.1) (6.12.2.2.2c)
- $M_{yc\ eff}$ = yield moment with respect to the compression flange of the effective cross-section determined as specified in Article D6.2 (kip-in.) (D6.6.3)
- M_{yt} = yield moment with respect to the tension flange determined as specified in Article D6.2 (kip-in.) (6.9.2.2.1)
- M_{yte} = yield moment with respect to the tension flange determined as specified in Article D6.2.1 or D6.2.3, as applicable, using the effective width of the compression flange, b_e , calculated as specified in Article 6.9.4.2.2b with F_{cr} taken equal to F_{yc} and including the width of the corner areas and flange extensions (kip-in.). The box-flange area of the gross cross-section shall not be reduced to account for shear lag in the calculation (C6.11.8.3)
- m = fatigue growth constant from Table 6.6.1.2.3-1 (6.6.1.2.5)
- N = total number of stress cycles over the fatigue design life; length of bearing, taken greater than or equal to k at end bearing locations (in.) (C6.6.1.2.5) (D6.5.2)
- NDT = nondestructive testing (6.6.1.2.3)
- N_b = concrete breakout resistance in tension of a single stud shear connector in cracked concrete (kip) (6.16.4.3)
- N_n = nominal tensile resistance of a single stud shear connector (kip) (6.16.4.3)
- N_r = factored tensile resistance of a single stud shear connector (kip) (6.16.4.3)
- N_s = number of shear planes per bolt; number of slip planes per bolt; number of shear planes per anchor rod (6.13.2.7) (6.13.2.8) (6.13.2.12)
- N_u = seismic axial force demand per stud at the support cross-frame or diaphragm location under consideration (kip) (6.14.4.3)
- n = number of stress range cycles per truck passage; number of intermediate brace points within the span under consideration; modular ratio of the concrete; short-term modular ratio; minimum number of shear connectors over the region under consideration; number of equally spaced flange longitudinal stiffeners; number of uniformly spaced internal reinforcing bars in a composite concrete-filled steel tube; number of longitudinal stiffeners (6.6.1.2.5) (6.7.4.2.2) (6.9.5.1) (6.10.1.1.1b) (6.10.10.4.1) (6.11.8.2.3) (C6.12.2.3.3) (E6.1.3)
- n_{ac} = number of additional shear connectors required in the regions of points of permanent load contraflexure for sections that are noncomposite in negative-flexure regions (6.10.10.3)
- n_g = number of girders within the span under consideration connected by diaphragms or cross-frames (6.7.4.2.2)
- n_ℓ = number of stud rows in a shear connector cluster along the longitudinal axis (6.10.10.1.2)
- $NSTM$ = nonredundant steel tension member (6.6.2.2)
- n_t = number of shear connectors in a transverse cross-section (6.10.10.1.2)
- P = unfactored axial dead load for a composite concrete-filled steel tube (kip); total nominal shear force in the concrete deck for the design of the shear connectors at the strength limit state (kip) (6.9.6.3.2) (6.10.10.4.1)
- P_{1n} = longitudinal force in the girder over an interior support for the design of the shear connectors at the strength limit state (kip) (6.10.10.4.2)
- P_{1p} = longitudinal force in the concrete deck at the point of maximum positive live load plus impact moment for the design of the shear connectors at the strength limit state (kip) (6.10.10.4.2)
- P_{2n} = longitudinal force in the concrete deck over an interior support for the design of the shear connectors at the strength limit state (kip) (6.10.10.4.2)
- P_{2p} = longitudinal force in the girder at the point of maximum positive live load plus impact moment for the design of the shear connectors at the strength limit state (kip) (6.10.10.4.2)
- P_c = plastic force in the compression flange used to compute the plastic moment (kip) (D6.1)
- P_{cr} = nominal compressive resistance of the member calculated from Eq. 6.9.4.1.1-1 or 6.9.4.1.1-2, as applicable, using A_g (kip) (6.9.4.2.2a)
- P_e = elastic critical buckling resistance determined as specified in Article 6.9.4.1.2 for flexural buckling, as specified in Article 6.9.4.1.3 for torsional buckling or flexural-torsional buckling, as applicable (kip); Euler buckling load (kip); elastic critical buckling resistance for flexural buckling of a composite concrete-filled steel tube (kip); elastic critical buckling resistance determined as specified in Article 6.14.2.8.4 for gusset plate buckling (kip) (6.9.4.1.1) (6.9.5.1) (6.9.6.3.2) (6.14.2.8.4)
- P_{csF} = elastic flexural buckling resistance of an individual stiffener strut (kip) (E6.1.3)
- P_{csT} = plate torsional stiffness contribution to the elastic buckling resistance of an individual stiffener strut (kip) (E6.1.3)

P_{fy}	=	design yield resistance of the flange at a point of splice (kip) (6.13.6.1.3b)
P_h	=	horizontal component of the flange force in the inclined bottom flange of a variable web depth member (kip) (C6.10.1.4)
P_t	=	statically equivalent concentrated lateral concrete deck overhang bracket force placed at the middle of the unbraced length (kip) (C6.10.3.4.1)
P_n	=	nominal bearing resistance on pin plates (kip); nominal compressive resistance (kip); nominal compressive resistance of a composite concrete-filled steel tube (kip); total longitudinal force in the concrete deck over an interior support for the design of the shear connectors at the strength limit state, taken as the lesser of either P_{1n} or P_{2n} (kip); nominal compressive resistance of an idealized Whitmore section (kip) (6.8.7.2) (6.9.2.1) (6.9.6.3.2) (6.10.10.4.2) (6.14.2.8.4)
P_{nR}	=	nominal compressive resistance provided by an individual laterally restrained longitudinal edge of a longitudinally stiffened plate (kip) (E6.1.3)
P_{ns}	=	nominal compressive resistance of an individual stiffener strut composed of the stiffener plus the tributary width of the longitudinally stiffened plate under consideration (kip) (E6.1.3)
P_{nsF}	=	nominal flexural buckling resistance of an individual stiffener strut (kip) (E6.1.3)
P_{nsp}	=	nominal compressive resistance of the compression flange calculated as specified in Article E6.1.3 (kip); nominal compressive resistance of a longitudinally stiffened component plate (kip) (6.11.8.2.3) (E6.1.3)
P_{ny}	=	nominal axial tensile resistance for yielding in the gross section (kip) (6.8.2.1)
P_o	=	nominal yield resistance = $F_y A_g$ (kip); compressive resistance of a composite concrete-filled steel tube column without consideration of buckling (kip) (6.9.4.1.1) (6.9.6.3.2)
P_{os}	=	nominal yield resistance given by Eq. E6.1.1-9 (kip) (E6.1.1)
P_p	=	total longitudinal force in the concrete deck at the point of maximum positive live load plus impact moment for the design of the shear connectors at the strength limit state, taken as the lesser of either P_{1p} or P_{2p} (kip) (6.10.10.4.2)
P_r	=	factored axial tensile resistance (kip); factored bearing resistance on pin plates (kip); for cross-sections subjected to axial tension, factored tensile rupture resistance of the net section based on Eq. 6.8.2.1-2; for cross-sections subjected to axial compression, factored tensile yield resistance of the cross-section based on Eq. 6.8.2.1-1 (kip); factored compressive resistance as specified in Article 6.9.2.1 (kip); factored compressive resistance of a composite concrete-filled steel tube (kip); factored axial resistance of bearing stiffeners (kip); factored compressive resistance of gusset plates (kip); factored resistance of piles in compression (ksi) (6.8.2.1) (6.8.7.2) (6.8.2.3.3) (6.9.2.2.1) (6.9.6.3.2) (6.10.11.2.4a) (6.14.2.8.4) (6.15.3.1)
P_{rb}	=	plastic force in the bottom layer of longitudinal deck reinforcement used to compute the plastic moment (kip) (D6.1)
P_{rs}	=	design yield resistance of the longitudinal deck reinforcement at a point of splice (kip) (C6.13.6.1.3b)
P_{rt}	=	plastic force in the top layer of longitudinal deck reinforcement used to compute the plastic moment (kip) (D6.1)
P_{ry}	=	factored tensile resistance based on tension yielding, obtained from Eq. 6.8.2.1-1 (kip) (6.8.2.3.1)
P_s	=	plastic compressive force in the concrete deck used to compute the plastic moment (kip) (D6.1)
P_T	=	total longitudinal force in the concrete deck between the point of maximum positive live load plus impact moment and the centerline of an adjacent interior support for the design of the shear connectors at the strength limit state, taken as the sum of P_p and P_n (kip) (6.10.10.4.2)
P_t	=	minimum required bolt tension (kip); plastic force in the tension flange used to compute the plastic moment (kip) (6.13.2.8) (D6.1)
P_u	=	factored tensile axial force (kip); maximum factored axial force at the cross-section containing the flange bolt holes taken as positive in tension and negative in compression (kip); factored compressive axial force throughout the member length in Eqs. 6.9.2.2.1-1 through 6.9.2.2.1-3 (kip); direct tension or shear force on a bolt due to the factored loads (kip); axial compressive force effect resulting from factored loads (kip) (6.8.2.3.1) (6.8.2.3.3) (6.9.2.2.1) (6.13.2.10.4) (6.13.2.11)
P_{up}	=	total factored longitudinal compression force in the plate under consideration, determined from a structural analysis considering the gross cross-section, including the longitudinal stiffeners, and including all sources of factored longitudinal normal compressive stresses from axial loading and from flexure (kip) (E6.1.5.2)
P_{ups}	=	factored axial force within a longitudinal stiffener strut, composed of the longitudinal stiffener and the tributary plate width, determined from a structural analysis considering the gross cross-section (kip) (E6.1.5.1)
P_v	=	vertical component of the flange force in the inclined bottom flange of a variable web depth member (kip) (C6.10.1.4)
P_w	=	plastic force in the web used to compute the plastic moment (kip) (D6.1)

P_{yeR}	=	effective yield load of an individual laterally restrained longitudinal edge of a longitudinally stiffened plate (kip) (E6.1.3)
P_{yes}	=	effective yield load of an individual stiffener strut (kip) (E6.1.3)
P_{ys}	=	yield load of an individual stiffener strut (kip) (E6.1.3)
p	=	center-to-center pitch between regularly spaced shear connectors or center-to-center pitch between shear connector clusters (in.) (6.10.10.1.2)
Q	=	first moment of the transformed short-term area of the concrete deck about the neutral axis of the short-term composite section, or optionally in regions of negative flexure of straight girders only, the first moment of the longitudinal reinforcement about the neutral axis of the composite section if the concrete is not considered to be effective in tension in computing the range of longitudinal stress (in. ³); first moment of one-half the effective box-flange area at an interior pier about the neutral axis of the effective internal diaphragm section (in. ³) (6.10.10.1.2) (C6.11.8.1.1)
Q_n	=	nominal shear resistance of a single shear connector (kip) (6.10.10.4.1)
Q_r	=	factored shear resistance of a single shear connector (kip) (6.10.10.4.1)
Q_u	=	prying tension per bolt due to the factored loads (kip); seismic shear demand per stud at the support cross-frame or diaphragm location under consideration due to the governing orthogonal combination of seismic shears (kip) (6.13.2.10.4) (6.16.4.3)
R	=	transition radius of welded attachments as shown in Table 6.6.1.2.3-1 (in.); girder radius at the centerline of the bridge (ft); minimum girder radius within a panel (ft); minimum girder radius over the lengths L_p and L_n (ft); reduction factor applied to the factored shear resistance of bolts passing through fillers; radius of curvature of the arch rib at the mid-depth of the web for the section under consideration (in.) (6.6.1.2.3) (6.7.2) (6.7.4.2.1) (6.10.10.4.2) (6.13.6.1.4) (6.14.4.1)
R_b	=	minimum web load-shedding factor within the unbraced length under consideration including the end cross-sections, determined as specified in Article 6.10.1.10.2; web load-shedding factor (6.10.1.6) (6.10.1.10.2)
R_f	=	compression flange slenderness factor (6.12.2.2.2c)
R_h	=	hybrid factor (6.10.1.10.1)
R_m	=	reverse curvature modification factor applied to C_b (C6.10.8.2.3b)
R_n	=	nominal resistance of a bolt, connection or connected material (kip) or (ksi); nominal resistance to a concentrated loading (kip) (6.13.2.2) (D6.5.2)
R_p	=	reduction factor for holes taken equal to 0.90 for bolt holes punched full size and 1.0 for bolt holes drilled full size or subpunched and reamed to size (6.8.2.1)
$(R_{pB})_n$	=	nominal bearing resistance on pins (kip) (6.7.6.2.2)
$(R_{pB})_r$	=	factored bearing resistance on pins (kip) (6.7.6.2.2)
R_{pc}	=	web plastification factor for the compression flange at the cross-section under consideration determined as specified in Article A6.2.1 or Article A6.2.2, as applicable; web plastification factor for the compression flange; web plastification factor for the compression flange determined as specified in Article A6.2.1 or Article A6.2.2, as applicable (6.10.1.6) (6.12.2.2.2c) (A6.3.2)
R_{pt}	=	web plastification factor for the tension flange (A6.1.4)
R_r	=	factored resistance of a bolt, connection or connected material (kip) or (ksi); factored resistance in tension of connection elements (kip); factored tensile resistance of gusset plates (kip) (6.13.2.2) (6.13.5.2) (6.14.2.8.5)
$(R_{sb})_n$	=	nominal bearing resistance for the fitted end of bearing stiffeners (kip) (6.10.11.2.3)
$(R_{sb})_r$	=	factored bearing resistance for the fitted end of bearing stiffeners (kip) (6.10.11.2.3)
R_u	=	factored concentrated load or bearing reaction (kip) (D6.5.2)
r	=	minimum radius of gyration (in.); radius to the mid-thickness of the tube (in.); radius of gyration of a built-up member about an axis perpendicular to a perforated plate (in.); outside radius of a half-round I-girder bearing stiffener (in.); radius of gyration of a longitudinal web stiffener including an effective width of web taken about the neutral axis of the combined section (in.); radius to the outside of the steel tube in a composite concrete-filled steel tube (in.) (6.8.4) (C6.9.2.2.2) (6.9.4.3.2) (6.10.11.2.2) (6.10.11.3.3) (C6.12.2.3.3)
r_1, r_2	=	reduction factors applied in the calculation of the nominal compressive resistance of noncomposite rectangular box cross-sections containing one or more flange elements in the direction associated with column flexural buckling in which the flange element or elements contain longitudinal stiffeners, and where $\lambda_{max} > \lambda_{cr}$ (E6.1.1)
r_b	=	radius to the center of the internal reinforcing bars in a composite concrete-filled steel tube (in.) (C6.12.2.3.3)

r_i	=	minimum radius of gyration of an individual component shape (in.); radius to the inside of the steel tube in a composite concrete-filled steel tube (in.) (C6.9.4.3.1) (C6.12.2.3.3)
r_{ib}	=	radius of gyration of an individual component shape relative to its centroidal axis parallel to the member axis of buckling (in.) (6.9.4.3.1)
r_m	=	radius to the center of the steel tube in a composite concrete-filled steel tube (in.) (C6.12.2.3.3)
r_n	=	nominal bearing pressure at bolt holes (ksi) (C6.13.2.9)
r_s	=	radius of gyration about the axis normal to the plane of buckling (in.); radius of gyration of a stiffener strut about an axis parallel to the plane of the stiffened plate (in.) (6.9.4.1.2) (E6.1.4)
r_t	=	effective radius of gyration for LTB (in.) (6.10.8.2.3b)
$r_{t\text{ eff}}$	=	radius of gyration for LTB for the prismatic section with the effective cross-section (in.) (D6.6.3)
r_{ts}	=	radius of gyration used in the determination of L_r (in.) (6.12.2.2.5)
r_x	=	radius of gyration about the x-axis (in.); radius of gyration about the geometric axis of the angle parallel to the connected leg (in.) (6.9.4.1.3) (6.9.4.4)
r_y	=	radius of gyration about the y-axis (in.); radius of gyration of the gross noncomposite box section about its minor principal axis, including any longitudinal stiffeners (in. ⁴) (6.9.4.1.3) (6.12.2.2.2e)
r_{yc}	=	radius of gyration of the compression flange with respect to a vertical axis in the plane of the web (in.) (C6.10.8.2.3b)
r_z	=	radius of gyration about the minor principal axis of the angle (in.) (6.9.4.4)
r_σ	=	desired bending stress ratio in a horizontally curved I-girder, taken equal to $ f_t/f_{bu} $ (C6.7.4.2.1)
$\bar{r}_o$	=	polar radius of gyration about the shear center (in.) (6.9.4.1.3)
S	=	beam or girder spacing (in.); elastic section modulus about the axis of bending (in. ³); elastic section modulus (in. ³) (6.7.4.2.2) (C6.12.2.2.1) (6.12.2.2.3)
S_g	=	elastic gross section modulus of gusset plates and splice plates (in. ³) (6.14.2.8.6)
S_n	=	elastic net section modulus of gusset plates and splice plates (in. ³) (6.14.2.8.6)
S_{LT}	=	long-term composite elastic section modulus (in. ³) (D6.2.2)
S_{NC}	=	noncomposite elastic section modulus (in. ³) (D6.2.2)
SRM	=	system redundant member (6.6.2.2)
S_{ST}	=	short-term composite elastic section modulus (in. ³) (D6.2.2)
S_t	=	minimum elastic section modulus about the axis of bending under consideration (in. ³) (6.8.2.3.3)
S_x	=	elastic section modulus to an inclined bottom flange of a variable web depth member (in. ³); elastic section modulus about the x-axis with respect to the tip of the tee stem or double-angle web legs, as applicable (in. ³); elastic section modulus about the x-axis (in. ³); section modulus about the major geometric axis (in. ³); (C6.10.1.4) (6.12.2.2.4b) (6.12.2.2.5) (6.12.2.2.7)
S_{xc}	=	elastic section modulus about the major axis of the section to the compression flange taken as M_{yc}/F_{yc} (in. ³); elastic section modulus about the major axis of the section to the compression flange (in. ³); elastic section modulus about the x-axis with respect to the tee flange or double-angle flange legs subject to compression, as applicable (in. ³) (6.9.2.2.1) (6.10.1.6) (6.12.2.2.4d)
S_{xce}	=	effective elastic section modulus about the axis of bending to the compression flange determined using the effective width for the compression flange, b_e , calculated as specified in Article 6.9.4.2.2b with F_{cr} taken equal to F_{yc} , and the gross area for the tension flange (in. ³) (6.12.2.2.2c)
$S_{xc\text{ eff}}$	=	elastic section modulus about the major axis of the section to the compression flange of the effective cross-section (in. ³) (D6.6.3)
S_{xt}	=	elastic section modulus about the major axis of the section to the tension flange taken as M_{yt}/F_{yt} (in. ³) (6.9.2.2.1)
S_{xte}	=	effective elastic section modulus about the axis of bending to the tension flange determined using the effective width for the compression flange, b_e , calculated as specified in Article 6.9.4.2.2 with F_{cr} taken equal to F_{yc} , and the gross area for the tension flange (in. ³) (6.12.2.2.2c)
S_y	=	elastic section modulus about the axis parallel with the web (in. ³) (6.12.2.2.1)
s	=	pitch of any two consecutive bolts in a staggered chain (in.); center-to-center pitch between studs within a shear connector cluster (in.); longitudinal spacing of transverse reinforcement in a concrete-encased shape (in.); spacing of bolts on a single line or in a staggered pattern adjacent to a free edge of an outside plate or shape (in.) (6.8.3) (6.10.10.1.2) (6.12.3.1) (6.13.2.6.2)
s_t	=	maximum transverse spacing between shear connectors on a composite box flange (in.) (6.11.10)
T	=	factored internal torque (kip-in.); factored torque (kip-in.); thickness of a washer (in.); base metal thickness of the thicker part joined in a fillet-welded connection given in Table 6.13.3.4-1 (in.) (C6.11.1.1) (6.11.3.2) (C6.13.2.7) (6.13.3.4)
T_n	=	nominal torsional resistance for noncomposite circular tubes and round HSS (kip-in.); nominal resistance of a bolt in axial tension or in combined axial tension and shear (kip) (6.12.1.2.3a) (6.13.2.2)

T_r	=	factored torsional resistance for noncomposite circular tubes and round HSS (kip-in.); factored resistance of a bolt in axial tension or in combined axial tension and shear (kip) (6.12.1.2.3a) (6.13.2.2)
T_u	=	factored torque (kip-in.); factored torque at the section under consideration (kip-in.); tensile force per bolt due to Load Combination Service II (kip) (C6.9.2.2.2) (6.12.1.2.3a) (6.13.2.11)
t	=	distance from the centroid of the section at the brace point under consideration to the centroid of the tension flange (in.); thickness of plate or plates (in.); element thickness (in.); thickness of the element under consideration (in.); wall thickness of a circular tube or round HSS (in.); wall thickness of the steel tube in a composite concrete-filled steel tube (in.); distance from the centroid of the noncomposite steel section under consideration to the centroid of the tension flange (in.); thickness of a half-round I-girder bearing stiffener (in.); wall thickness of the tube (in.); thickness of each plate of the box-section member (in.); thickness of an individual double angle web leg (in.); width of the rectangular bar parallel to the axis of bending (in.); thickness of the thinner outside plate or shape (in.); thickness of the connected material (in.); thickness of the thinnest connected part (in.); thickness of the cross-section plate component under consideration in an arch rib (in.); thickness of a longitudinally unstiffened plate (in.); thickness of a longitudinally stiffened plate (in.); longitudinal stiffener plate element thickness (in.) (6.7.4.2.2) (C6.7.4.3) (6.9.4.2.1) (6.9.4.2.2a) (6.9.4.2.2c) (6.9.6.2) (6.10.3.4.2) (6.10.11.2.2) (6.12.1.2.3b) (6.12.2.2.2e) (6.12.2.2.4e) (6.12.2.2.7) (6.13.2.6.2) (6.13.2.9) (6.13.2.10.4) (6.14.4.1) (E6.1.1) (E6.1.2) (E6.1.4)
t_b	=	thickness of a fictional tube modeling the internal reinforcement in a composite concrete-filled steel tube (in.); thickness of the flange transmitting the concentrated force in a rigid-frame connection (in.) (C6.12.2.3.3) (6.13.7.2)
t_c	=	thickness of the flange of the member to be stiffened in a rigid-frame connection (in.) (6.13.7.2)
t_f	=	flange thickness (in.); thickness of the flange plate element or longitudinally stiffened flange plate panel under consideration (in.); thickness of the single top flange under consideration, or thickness of the box flange under consideration, as applicable (in.); thickness of the flange plate element or longitudinally stiffened flange plate panel under consideration (in.); thickness of the flange under consideration. For HSS, the provisions of Article 6.12.1.2.4 apply (in.); tee flange thickness or thickness of double-angle flange legs, as applicable (in.); thickness of the flange resisting a concentrated load or bearing reaction (in.) (C6.9.4.1.3) (6.9.4.5) (6.11.2.2) (6.11.3.2) (6.12.2.2.2b) (6.12.2.2.4d) (D6.5.3)
t_{fc}	=	thickness of the compression flange (in.); thickness of the compression flange plate element or longitudinally stiffened compression-flange plate panel under consideration (in.) (6.10.1.10.2) (6.11.7.2.2)
$t_{fc\ eff}$	=	effective flange thickness corresponding to the flange subject to flexural compression within the unbraced length under consideration (in.) (D6.6.3)
$t_{f,small}$	=	flange thickness at the smallest cross-section within the unbraced length under consideration (in.) (D6.6.3)
t_{ft}	=	thickness of the tension flange (in.); thickness of the tension-flange plate element or longitudinally stiffened tension-flange plate panel under consideration (in.) (6.10.9.3.2) (6.11.7.2.2)
$t_{ft\ eff}$	=	effective flange thickness corresponding to the flange subject to flexural tension within the unbraced length under consideration (in.) (D6.6.3)
t_{f2}	=	flange thickness at the second smallest cross-section within the unbraced length under consideration (in.) (D6.6.3)
t_g	=	gusset plate thickness (6.14.2.8.4)
t_{haunch}	=	thickness of the concrete haunch measured from the top of the web to the bottom of the concrete deck (in.) (C6.13.6.1.3b)
t_p	=	thickness of a loaded discontinuous plate element (in.); thickness of a projecting stiffener element (in.); thickness of a projecting plate stiffener element (in.) (6.6.1.2.5) (6.10.11.1.2) (6.10.11.2.2)
t_s	=	thickness of a connection plate or projecting leg of an end angle (in.); thickness of a concrete deck (in.) (6.7.4.2.2) (6.10.1.10.2)
t_{sp}	=	thickness of a longitudinally stiffened plate (in.); thickness of a stiffened plate (in.) (E6.1.3) (E6.1.5.2)
t_w	=	web thickness (in.); thickness of the web plate element under consideration (in.); thickness of the webs. For box sections with different thickness webs, the smaller web thickness. For HSS, the provisions of Article 6.12.1.2.4 apply (in.); thickness of the web (in.); thickness of the tee stem (in.); thickness of the web to be stiffened in a rigid-frame connection (in.); web thickness of an arch rib (in.) (6.7.4.2.2) (6.9.4.5) (6.12.2.2.2b) (6.12.2.2.4e) (6.12.2.2.5) (6.13.7.2) (6.14.4.2)
$t_{w\ eff}$	=	effective web thickness within the unbraced length under consideration (in.) (D6.6.3)
$t_{w,small}$	=	web thickness at the smallest cross-section within the unbraced length under consideration (in.) (D6.6.3)
U	=	reduction factor to account for shear lag in connections subjected to a tension load; reduction factor to account for shear lag; 1.0 for components in which force effects are transmitted to all elements, and as specified in Article 6.8.2.2 for other cases (6.6.1.2.3) (6.8.2.1)

U_{bs}	=	reduction factor for block shear rupture resistance taken equal to 0.50 when the tension stress is nonuniform and 1.0 when the tension stress is uniform (6.13.4)
V	=	additional shear force for built-up members with perforated plates (kip); factored vertical shear force in the internal interior-pier diaphragm of a box section due to flexure plus St. Venant torsion (kip) (6.9.4.3.2) (C6.11.8.1.1)
V_c	=	nominal shear resistance provided by the concrete infill (kips) (6.12.3.2.2)
V_{cr}	=	shear-yielding or shear buckling resistance (kip); web shear-yielding or shear-buckling resistance of the web panel under consideration (kip) (6.10.3.3) (6.10.11.1.3)
V_f	=	vertical shear force range under the Fatigue Load Combination (kip) (6.10.10.1.2)
V_{fat}	=	longitudinal fatigue shear range per unit length (kip/in.) (6.10.10.1.2)
V_n	=	nominal shear resistance (kip); nominal shear-yielding or shear-buckling plus post-buckling tension-field action resistance of the web panel under consideration (kip) (6.10.9.1) (6.10.11.1.3)
V_{ni}	=	the nominal interface shear resistance determined as specified in Article 5.7.4 (C6.16.4.2)
V_p	=	plastic shear force (kip) (6.10.9.2)
V_r	=	factored flexural shear resistance (kip); factored shear resistance of gusset plates (kip) (6.12.1.2.3) (6.14.2.8.3)
V_s	=	nominal shear resistance provided by the steel tube (kips) (6.12.3.2.2)
V_{sr}	=	horizontal fatigue shear range per unit length (kip/in.); vector sum of the horizontal fatigue shear range and the torsional fatigue shear range in the concrete deck for a composite box flange (kip/in.) (6.10.10.1.2) (6.11.10)
V_u	=	shear due to the factored loads (kip); shear in the web acting on the noncomposite section under consideration due to the factored load for constructability specified in Article 3.4.2.1 (kip); maximum shear due to the factored loads in the web panel under consideration (kip); vertical shear due to the factored loads on one inclined web of a box section (kip); for noncomposite circular tubes, including round HSS, factored flexural shear at the section under consideration. For noncomposite rectangular box-section members subject to torsion, including square and rectangular HSS, the factored shear in each web element shall be taken as the sum of the flexural and St. Venant torsional shears (kip) (6.7.6.2.1) (6.10.3.3) (6.10.11.1.3) (6.11.9) (6.12.1.2.3a)
V_{ul}	=	shear due to the factored loads along one inclined web of a box section (kip) (6.11.9)
V_{ut1}	=	first-order force transferred by the attachment of a longitudinal stiffener due to any directly applied factored loads on the stiffener perpendicular to the plane of the stiffened plate (kip) (CE6.1.5.1)
V_{utl}	=	first-order force in the direction perpendicular to the plane of the stiffened plate at the attachment of a longitudinal stiffener due to any directly applied factored loads (kip) (CE6.1.5.1)
$V_{ux} V_{uy}$	=	factored biaxial flexural shear forces (kip) (C6.9.2.2.2)
W	=	total weight of the deck, steel girders, and, where applicable, cap beam, plus one-half the column weight within the span under consideration (kip) (6.16.4.2)
W_{px}	=	weight of the deck plus one-half of the weight of the steel girders in the span under consideration (kip) (6.16.4.2)
w	=	leg size of the reinforcement or contour fillet, if any, in the direction of the thickness of the loaded discontinuous plate element (in.); center-to-center distance between the top of the webs of a tub section (in.); plate width (in.); width of the plate between the centerlines of the individual longitudinal stiffeners and/or between the centerline of a longitudinal stiffener and the inside of the laterally restrained longitudinal edge of a longitudinally stiffened plate, as applicable (in.); effective length of deck assumed acting radial to the girder (in.); width of the box-flange plate between the centerlines of the individual longitudinal stiffeners and/or between the centerline of a longitudinal stiffener and the inside of the laterally restrained longitudinal edge of a longitudinally stiffened plate element under consideration, as applicable (in.); widths of the plate between the centerlines of the individual longitudinal stiffeners and/or between the centerline of a longitudinal stiffener and the inside of the laterally restrained longitudinal edge of a longitudinally stiffened plate, as applicable, equal to the tributary width in the case of equally spaced longitudinal stiffeners (in.) (6.6.1.2.5) (C6.7.5.3) (6.8.2.2) (6.9.4.5) (6.10.10.1.2) (6.11.2.2) (6.12.2.2.2b)
w_e	=	effective width of the plate between the longitudinal stiffeners or between a longitudinal stiffener and the laterally restrained longitudinal edge of the longitudinally stiffened plate under consideration, as applicable (in.) (E6.1.3)
w_g	=	girder spacing for a two-girder system or the distance between the two exterior girders of the unit for a three-girder system (in.) (6.10.3.4.2)
w_h	=	width of haunch perpendicular to bridge span axis (in.) (6.16.4.3)
w_{max}	=	larger of the width of the flange between flange longitudinal stiffeners or the distance from a web to the nearest flange longitudinal stiffener (in.) (6.11.8.2.3)

x_o	=	distance along the x -axis between the shear center and centroid of the cross-section (in.) (6.9.4.1.3)
$\bar{x}$	=	distance from the centroid of the member to the surface of the gusset or connection plate (in.); connection eccentricity used in calculating the shear lag reduction factor, U (in.) (6.6.1.2.3) (6.8.2.2)
x_{inf}	=	distance between the point of contraflexure and the end of the unbraced length under consideration with the smaller magnitude of moment, M_{small} (in.) (C6.10.8.2.3b)
x_{small}	=	fraction of the total unbraced length under consideration comprising the smallest dimension of D , b_f , t_f , and/or t_w , as applicable (D6.6.3)
Y	=	bolt transition thread length (in.) (C6.13.2.7)
y	=	distance from the center of the steel tube to the neutral axis for a given stress state in a composite concrete-filled steel tube (in.) (C6.12.2.3.3)
y_o	=	distance along the y -axis between the shear center and centroid of the cross-section (in.) (6.9.4.1.3)
$\bar{y}$	=	distance from the plastic neutral axis to the top of the element where the plastic neutral axis is located (in.) (D6.1)
Z	=	horizontal curvature parameter for determining required longitudinal web stiffener rigidity; plastic section modulus (in. ³); plastic section modulus of the steel section of a composite concrete-encased shape about the axis of bending (in. ³) (6.10.11.3.3) (6.12.2.2.3) (6.12.2.3.1)
Z_r	=	shear fatigue resistance of an individual shear connector (kip) (6.10.10.1.2)
Z_x	=	plastic section modulus about the x -axis (in. ³) (6.12.2.2.4b)
Z_y	=	plastic section modulus about the axis parallel with the web (in. ³) (6.12.2.2.1)
α	=	separation ratio = $h/2r_{ib}$; (6.9.4.3.1)
β	=	factor equal to two times the area of the web, based on D_n divided by A_{fn} used in computing the hybrid factor; factor defining the approximate ratio of D_p to $D_f/7.5$ at which a composite section in positive flexure reaches M_p ; horizontal curvature correction factor for longitudinal web stiffener rigidity; angle between the flanges of the I-section for a linear variation in the web depth, or angle of the chord between the bottom of the web at each end of the unbraced length for a concave parabolic variation in web depth, taken as positive in all cases (degrees) (6.10.1.10.1) (C6.10.7.1.2) (6.10.11.3.3) (D6.6.2.1)
β_{br}	=	brace stiffness of the diaphragm or cross-frame that restrains twist of a beam or girder (kip-in./rad.) (6.7.4.2.2)
$\beta_{br,skew}$	=	brace stiffness of an intermediate diaphragm or cross-frame brace skewed relative to a line normal to the longitudinal axis of the bridge (i.e., stiffness in the plane of the cross-frame or diaphragm multiplied by $\cos^2\theta$) (kip-in./rad.) (C6.7.4.2.2)
β_g	=	effective in-plane girder stiffness for stability bracing (kip-in./rad.) (6.7.4.2.2)
β_{sec}	=	cross-sectional distortion stiffness for stability bracing (kip-in./rad.); effective continuous torsional bracing stiffness provided by the combination of rigid restraint from the bridge deck plus the distortional stiffness of the I-section web (kip-in./rad) (6.7.4.2.2) (CA6.3.3.2)
$\beta_{sec i}$	=	cross-sectional distortion stiffness term for the portions of the web above and below a less than full-depth connection plate or end angle, or above and below the cross-frame or diaphragm member (kip-in./rad.) (C6.7.4.2.2)
$(\beta_T)_{act}$	=	actual overall stiffness of a torsional brace system (kip-in./rad) (6.7.4.2.2)
$(\beta_T)_{req}$	=	required stiffness of a torsional brace system (kip-in./rad) (6.7.4.2.2)
γ	=	load factor specified in Table 3.4.1-1; the ratio of A_f to A_p for filler plate design (6.6.1.2.2) (6.13.6.1.4)
γ_e	=	elastic LTB load ratio calculated using one of the methods specified in Article D6.6 (6.10.8.2.3c)
γ_p	=	the maximum load factor for DC specified in Table 3.4.1-2, or the maximum load factor specified in Article 3.4.2.1 for DC and any construction loads that are applied to the fully erected steelwork (C6.7.2)
Δ	=	reduction factor applied to the factored axial resistance to account for the effect of torsional and/or flexural shear in a noncomposite box-section member or circular tube; reduction factor for the maximum stress in a box flange (6.8.2.3.2) (6.11.3.2)
(Δf)	=	live load stress range due to the passage of the fatigue load (ksi) (6.6.1.2.2)
$(\Delta F)^{C_n}$	=	nominal fatigue resistance for detail category C (ksi) (6.6.1.2.5)
$(\Delta F)_n$	=	nominal fatigue resistance (ksi) (6.6.1.2.2)
$(\Delta F)_{TH}$	=	constant-amplitude fatigue threshold taken from Table 6.6.1.2.3-1 (ksi) (6.6.1.2.5)
Δ_x, Δ_y	=	reduction factors applied to the factored flexural resistance about the x - and y -axes, respectively, to account for the effect of torsional and/or flexural shear in a noncomposite box-section member or circular tube (6.8.2.3.2)
η	=	load modifier related to ductility, redundancy and operational importance (C6.6.1.2.2)
λ	=	slenderness, b_f/t_f , w/t_f , or D/t_w , of the slender flange or web plate element or longitudinally stiffened plate panel under consideration; normalized column slenderness factor (6.9.4.5) (6.9.5.1)

λ_f	=	slenderness ratio for the compression flange; slenderness, b_{fl}/t_f or w/t_f , of the flange plate element or longitudinally stiffened plate panel under consideration, as applicable; slenderness ratio for the flange; compression flange slenderness = b_{fl}/t_{fc} ; flange slenderness = $b_f/2t_f$ for tees and b_f/t_f for double angles; flange slenderness of the channel = b_f/t_f (6.10.8.2.2) (6.11.8.2.2a) (6.12.2.2.1) (6.12.2.2.2c) (6.12.2.2.4d) (6.12.2.2.5)
λ_{max}	=	maximum w/t of the panels within a longitudinally stiffened flange plate (E6.1.1)
λ_p	=	limiting slenderness ratio for the box flange (6.11.10)
λ_{pf}	=	limiting slenderness ratio for a compact flange (6.10.8.2.2)
λ_{pw}	=	limiting slenderness for a compact web (6.12.2.2.2c)
$\lambda_{pw(Dc)}$	=	limiting slenderness ratio for a compact web corresponding to $2D_c/t_w$ (A6.2.2)
$\lambda_{pw(Dcp)}$	=	limiting slenderness ratio for a compact web corresponding to $2D_{cp}/t_w$ (A6.2.1)
λ_r	=	width-to-thickness or slenderness ratio limit as specified in Table 6.9.4.2.1-1; nonslender limit for longitudinally stiffened plate panels defined in Article E6.1.2; corresponding width-to-thickness ratio limit for the longitudinal stiffener plate element under consideration (6.9.4.2.1) (E6.1.1) (E6.1.4)
λ_{rf}	=	limiting slenderness ratio for a noncompact flange (6.10.8.2.2)
λ_{rw}	=	limiting slenderness ratio for a noncompact web, expressed in terms of $2D_c/t_w$; limiting slenderness ratio for a noncompact web (6.10.1.10.2) (6.10.6.2.3)
λ_{rwD}	=	limiting slenderness ratio for a noncompact web, expressed in terms of D/t_w (6.10.1.10.2)
λ_w	=	web slenderness; slenderness ratio for the web, based on the elastic moment (6.12.2.2.2c) (A6.2.2)
ψ_{ed}	=	edge modification factor for stud shear connectors (6.16.4.3)
ψ_g	=	group effect modification factor for transverse or longitudinal spacing (6.16.4.3)
ρ	=	factor equal to the smaller of F_{yw}/f_n and 1.0 used in computing the hybrid factor (6.10.1.10.1)
ρ_t	=	the larger of F_{yw}/F_{crs} and 1.0 (6.10.11.1.3)
ρ_{Top}	=	degree of monosymmetry parameter (C6.10.8.2.3b)
ρ_w	=	shear ratio used in the design of transverse stiffeners adjacent to web panels subject to post-buckling tension-field action (6.10.11.1.3)
θ	=	angle of a skewed intermediate diaphragm or cross-frame relative to a line normal to the longitudinal axis of the bridge (degrees); angle of inclination of the bottom flange of a variable web depth member (degrees); angle of inclination of the web plate of a box section to the vertical (degrees); framing angle of compression member relative to an adjoining member in a gusset-plate connection (C6.7.4.2.2) (C6.10.1.4) (6.11.9) (6.14.2.8.3)
θ_b	=	angle defining the length c_b for a given stress state in a composite concrete-filled steel tube (radians) (C6.12.2.3.3)
θ_p	=	plastic rotation at an interior-pier section (radians) (B6.6.2)
θ_{RL}	=	plastic rotation at which the moment at an interior-pier section nominally begins to decrease with increasing θ_p (radians) (B6.6.2)
θ_s	=	angle defining the length c for a given stress state in a composite concrete-filled steel tube (radians) (C6.12.2.3.3)
ν	=	Poisson's ratio = 0.3 (E6.1.3)
σ_{flg}	=	range of longitudinal fatigue stress in the bottom flange without consideration of flange lateral bending (ksi) (6.10.10.1.2)
ϕ	=	resistance factor; resistance factor applied to the modulus of rupture of the concrete (6.5.4.2) (6.10.1.7)
ϕ_b	=	resistance factor for bearing (6.5.4.2)
ϕ_{bb}	=	resistance factor for bolts bearing on material (6.5.4.2)
ϕ_{bs}	=	resistance factor for block shear (6.5.4.2)
ϕ_c	=	resistance factor for axial compression and combined axial compression and flexure (6.5.4.2)
ϕ_{cg}	=	resistance factor for truss gusset plate compression (6.5.4.2)
ϕ_{cs}	=	resistance factor for truss gusset chord splice (6.5.4.2)
ϕ_{da}	=	resistance factor during pile driving (6.5.4.2)
ϕ_{e1}	=	resistance factor for shear on the effective area of the weld metal in complete penetration welds; resistance factor for tension normal to the effective area of the weld metal in partial penetration welds (6.5.4.2)
ϕ_{e2}	=	resistance factor for shear parallel to the axis of the weld metal in partial penetration welds; resistance factor for shear in the throat of the weld metal in fillet welds (6.5.4.2)
ϕ_f	=	resistance factor for flexure (6.5.4.2)
ϕ_s	=	resistance factor for shear in bolts (6.5.4.2)
ϕ_{sb}	=	resistance factor for stability bracing (6.5.4.2)

ϕ_{sc}	=	resistance factor for shear connectors (6.5.4.2)
ϕ_{sd}	=	resistance factor for shakedown (CB6.4.2.1)
ϕ_{st}	=	resistance factor for shear connectors in tension (6.5.4.2)
ϕ_T	=	resistance factor for torsion (6.5.4.2)
ϕ_t	=	resistance factor for tension in bolts (6.5.4.2)
ϕ_u	=	resistance factor for fracture on the net section of tension members (6.5.4.2)
ϕ_v	=	resistance factor for shear (6.5.4.2)
ϕ_{vu}	=	resistance factor for shear rupture of connection elements (6.5.4.2)
ϕ_{vy}	=	resistance factor for truss gusset plate shear yielding (6.5.4.2)
ϕ_w	=	resistance factor for web crippling (6.5.4.2)
ϕ_y	=	resistance factor for yielding on the gross section of tension members (6.5.4.2)
Ω	=	shear yield reduction factor for gusset plates (6.14.2.8.3)
χ	=	nonprismatic geometry modification factor; reduction factor applied to the nominal compressive resistance of noncomposite rectangular box cross-sections containing one or more longitudinally stiffened flange plates in the direction associated with column flexural buckling, and where $\lambda_{max} > \lambda_r$ (D6.6.2) (E6.1.1)
$\sum_{lusp}$	=	summation over all longitudinally unstiffened cross-section plates (6.9.4.2.2a)
$\sum_c$	=	summation over all the corner areas of a noncomposite box-section member (6.9.4.2.2a)
$\sum_{lsp}$	=	summation over all the longitudinally stiffened cross-section plates (E6.1.1)

6.4—MATERIALS

6.4.1—Structural Steels

Structural steels shall conform to the requirements specified in Table 6.4.1-1, and the design shall be based on the minimum properties indicated.

The modulus of elasticity and the thermal coefficient of expansion of all grades of structural steel shall be assumed as 29,000 ksi and 6.5×10^{-6} in./in./°F, respectively.

C6.4.1

The term “yield strength” is used in these Specifications as a generic term to denote either the minimum specified yield point or the minimum specified yield strength.

The yield strength in the direction parallel to the direction of rolling is of primary interest in the design of most steel structures. In welded bridges, notch toughness is of equal importance. Other mechanical and physical properties of rolled steel, such as anisotropy, ductility, formability, and corrosion resistance, may also be important to ensure the satisfactory performance of the structure.

No specification can anticipate all of the unique or especially demanding applications that may arise. The literature on specific properties of concern and appropriate supplementary material production or quality requirements, provided in the AASHTO and ASTM Materials Specifications and the AASHTO/AWS D1.5M/D1.5 *Bridge Welding Code*, should be considered if appropriate.

AASHTO M 270M/M 270 (ASTM A709/A709M), Grade High-Performance Steel (HPS) 70W, has replaced AASHTO M 270M/M 270 (ASTM A709/A709M), Grade 70W, and AASHTO M 270M/M 270 (ASTM A709/A709M), Grade HPS 100W, has replaced AASHTO M 270M/M 270 (ASTM A709/A709M), Grade 100 and 100W in Table 6.4.1-1. The intent of these replacements is to encourage the use of HPS over the older bridge steels of the same strength level due to its enhanced properties. The older steels are still available,

AASHTO M 270M/M 270, Grade 36 (ASTM A709/A709M, Grade 36), may be used in thicknesses over 4.0 in. for nonstructural applications or bearing assembly components.

Quenched-and-tempered alloy steel structural shapes and seamless mechanical tubing with a specified maximum tensile strength not exceeding 140 ksi for structural shapes or 145 ksi for seamless mechanical tubing may be used, provided that:

- the material meets all other mechanical and chemical requirements of AASHTO M 270M/M 270 (ASTM A709/A709M), Grade HPS 100W, and
- the design is based upon the minimum properties specified for AASHTO M 270M/M 270 (ASTM A709/A709M), Grade HPS 100W.

Except as specified herein, structural tubing shall be either cold-formed welded or seamless tubing conforming to ASTM A1085/A1085M, ASTM A500/A500M, Grade B or Grade C, or ASTM A847/A847M; or hot-formed welded or seamless tubing conforming to ASTM A501/501M or ASTM A618/A618M.

Thickness limitations relative to rolled shapes and groups shall comply with ASTM A6/A6M. Steel tubing for composite Concrete-Filled Steel Tubes (CFSTs) designed according to the provisions of Article 6.9.6 shall conform to the requirements of:

- American Petroleum Institute (API) Specification 5L, minimum Grade X42, PSL1 or PSL2, or
- ASTM A252/A252M, Grade 3, with all welds satisfying the requirements of the current version of the AWS D1.1/D1.1M *Structural Welding Code—Steel*.

but are not recommended for use and should be used only with the approval of the Owner. The maximum available plate lengths of AASHTO M 270M/M 270 (ASTM A709/A709M), Grade HPS 70W and HPS 100W, are a function of the processing of the plate, with longer lengths of Grade HPS 70W produced as as-rolled plate. The maximum available plate lengths of these steels should be determined in consultation with the material producers.

ASTM A500/A500M cautions that structural tubing manufactured to that specification may not be suitable for applications involving dynamically loaded elements in welded structures where low-temperature notch-toughness properties may be important. As such, the use of this material should be carefully examined with respect to its specific application in consultation with the Owner. Where this material is contemplated for use in applications where low-temperature notch-toughness properties are deemed important, consideration should be given to requiring that the material satisfy the Charpy V-notch-toughness requirements specified in Article 6.6.2. ASTM A1085/A1085M is an improved specification for cold-formed welded carbon steel HSS that is more suitable for dynamically loaded structures.

Table 6.4.1-1—Mechanical Properties of Structural Steel by Shape, Strength, and Thickness

AASHTO Designation	M 270M/ M 270 Grade 36	M 270M/ M 270 Grade 50	M 270M/ M 270 Grade 50S	M 270M/ M 270 Grade 50W	M 270M/ M 270 Grade HPS 50W	M 270M/ M 270 Grade HPS 70W	M 270M/ M 270 Grade HPS 100W	
Equivalent ASTM Designation	A709/ A709M Grade 36	A709/ A709M Grade 50	A709/ A709M Grade 50S	A709/ A709M Grade 50W	A709/ A709M Grade HPS 50W	A709/ A709M Grade HPS 70W	A709/ A709M Grade HPS 100W

Specified Minimum Yield Point or Specified Minimum Yield Strength, F_y , ksi	36	50	50	50	50	70	100	90

6.4.2—Pins, Rollers, and Rockers

Steel for pins, rollers, and expansion rockers shall conform to the requirements in Table 6.4.2-1, Table 6.4.1-1, or Article 6.4.7.

Expansion rollers shall be not less than 4.0 in. in diameter.

Table 6.4.2-1—Minimum Mechanical Properties of Pins, Rollers, and Rockers by Size and Strength

AASHTO Designation with Size Limitations	M 169 4.0 in. in dia. or less	M 102M/ M 102 to 20.0 in. in dia.	M 102M/ M 102 to 20.0 in. in dia.	M 102M/ M 102 to 10.0 in. in dia.	M 102M/ M 102 to 20.0 in. in dia.

Specified Minimum Yield Point, F_y , ksi	36	33	37.5	50	50

6.4.3—Bolts, Nuts, and Washers**6.4.3.1—High-Strength Structural Fasteners***6.4.3.1.1—High-Strength Bolts*

High-strength bolts used as structural fasteners shall conform to ASTM F3125/F3125M or ASTM F3148. The specified minimum tensile strengths of high-strength bolts shall be taken as specified in Table 6.4.3.1.1-1.

Type 3 bolts shall be used with weathering steels.

Corrosion-resistant coatings may be applied to high-strength bolts, as specified in ASTM F3125/F3125M and ASTM F3148.

Table 6.4.3.1.1-1—Specified Minimum Tensile Strengths

Bolt	Specified Minimum Tensile Strength, ksi
ASTM F3125 Grade A325	120
ASTM F3125 Grade F1852	120
ASTM F3148 Grade 144	144
ASTM F3125 Grade A490	150
ASTM F3125 Grade F2280	150

C6.4.3.1.1

The ASTM F3125/F3125M standard bundles the previous ASTM A325, A325M, A490, A490M, F1852, and F2280 standards together and only the ASTM F3125/F3125M standard will be maintained moving forward. ASTM F3125/F3125M Grades F1852 and F2280 are the “twist-off” equivalents of Grades A325 and A490, respectively.

The ASTM F3148 standard covers high-strength bolt assemblies with fixed-spline drives that are intended to be installed with a torque-and-angle installation method, also referred to as the combined installation method.

The Engineer should refer to the latest versions of ASTM F3125/F3125M and ASTM F3148 for permissible coating options. As of 2022, high-strength bolts with a specified minimum tensile strength of 120 ksi may be mechanically galvanized per ASTM B695, hot-dip galvanized per ASTM F2329, or coated with zinc/aluminum coatings per ASTM F1136/F1136M, ASTM F2833, or ASTM F3019/F3019M. High-strength bolts with a specified minimum tensile strength of 144 ksi may be mechanically galvanized per ASTM B695 or coated with zinc/aluminum coatings per ASTM F1136/F1136M or ASTM F2833. High-strength bolts with a specified minimum tensile strength of 150 ksi may be coated with zinc/aluminum coatings per ASTM F1136/F1136M, ASTM F2833, or ASTM F3019/F3019M. Galvanizing is not an acceptable option for high-strength bolts with a specified minimum tensile strength of 150 ksi.

Rotational capacity testing of the fastener assemblies by the Manufacturer is required in accordance with Annex A2 of ASTM F3125/F3125M for Grade A325 and A490 fastener assemblies and in accordance with Annex A1 of ASTM F3148 for Grade 144 fastener assemblies, as specified in Article 17.7.1.1 of the AASHTO *LRFD Steel Bridge Fabrication Specifications*.

Alternative fasteners satisfying the requirements of ASTM F3125/F3125M or ASTM F3148 may be used subject to the approval of the Engineer.

6.4.3.1.2—Nuts Used with High-Strength Bolts

Nuts used with high-strength bolts shall be as listed in ASTM F3125/F3125M or ASTM F3148, as recommended or suitable for the bolt.

6.4.3.1.3—Washers Used with High-Strength Bolts

Hardened washers used with high-strength bolts shall be as listed in ASTM F3125/F3125M or ASTM F3148 as recommended or suitable for the bolt.

6.4.3.1.4—Direct Tension Indicators

Direct tension indicators (DTIs) conforming to the requirements of ASTM F959/F959M may be used in conjunction with bolts, nuts, and washers. Captive DTI/nuts shall be considered permissible for use, provided both the DTI and hardened heavy hex nut meet the mechanical property requirements of their respective ASTM standards. DTIs that incorporate a self-indicating feature shall also be considered permissible for use. The use of the self-indicating feature to replace the use of feeler gauges shall be subject to the approval of the Engineer. DTIs installed over oversize or slotted holes in an outer ply shall satisfy the applicable provisions of Article 6.13.2.3.2.

6.4.3.2—Low-Strength Steel Bolts

Low-strength steel bolts used as structural fasteners shall conform to ASTM A307 Grade A or B or an equivalent alternative subject to the approval of the Engineer. The specified minimum tensile strength of ASTM A307 bolts shall be taken as 60 ksi.

6.4.3.3—Fasteners for Structural Anchorage**6.4.3.3.1—Anchor Rods**

Anchor rods shall conform to ASTM F1554.

6.4.3.3.2—Nuts Used with Anchor Rods

Nuts used with ASTM F1554 anchor rods shall conform to ASTM A563 or ASTM A194/A194M Grade 2H.

Nuts to be galvanized shall be heat treated Grade DH or DH3. All galvanized nuts should be lubricated with a lubricant containing a visible dye in accordance with ASTM A563, Supplementary Requirements S1 and S2.

6.4.4—Stud Shear Connectors

Welded stud shear connectors shall satisfy all applicable requirements of the AASHTO/AWS D1.5M/D1.5 *Bridge Welding Code*, and shall have a specified minimum yield and tensile strength of 50.0 ksi and 60.0 ksi, respectively.

C6.4.3.1.4

DTIs are washers with protrusions on one face that measure load by compressing the protrusions on the DTI with a proportional reduction in the gap in the spaces between the protrusions. Attaining the required tension is verified by the number of “gauge refusals,” which are gaps that are too tight to permit the insertion of a feeler gauge of the prescribed thickness.

A DTI affixed to a hardened heavy hex nut by the fastener manufacturer is referred to as a captive DTI/nut. An assembly which incorporates a self-indicating feature to signal sufficient compression of the protrusions is referred to as a self-indicating DTI.

Installation provisions and verification procedures for DTIs are covered in Article 17.7 of the AASHTO *LRFD Steel Bridge Fabrication Specifications*.

C6.4.3.2

Low-strength steel bolts, also referred to as unfinished, common, machine, ordinary, or rough bolts, are typically designated as ASTM A307 bolts. The ASTM standard for A307 bolts covers two grades of fasteners, Grades A and B. An equivalent alternative may be used for these bolts subject to the approval of the Engineer.

C6.4.3.3.1

Fasteners for structural anchorage are covered in a separate article so that other requirements for high-strength bolts are not applied to anchor rods. The term “anchor rods,” which is used in these Specifications, is considered synonymous with the term “anchor bolts,” which has also been used.

C6.4.4

Specifications for material, manufacturing, physical properties, certification, and welding of stud shear connectors are provided in the AASHTO/AWS D1.5M/D1.5 *Bridge Welding Code*.

6.4.5—Weld Metal

Weld metal shall conform to the requirements of the AASHTO/AWS D1.5M/D1.5 *Bridge Welding Code*.

C6.4.5

The AWS designation systems are not consistent. For example, there are differences between the system used for designating electrodes for shielded metal arc welding and the system used for designating submerged arc welding. Therefore, when specifying weld metal and/or flux by AWS designation, the applicable specification should be reviewed to ensure a complete understanding of the designation reference.

6.4.6—Cast Metal

6.4.6.1—Cast Steel and Ductile Iron

Cast steel shall conform to one of the following:

- AASHTO M 103M/M 103 (ASTM A27/A27M), Grade 70-36, unless otherwise specified;
- AASHTO M 163M/M 163 (ASTM A743/A743M) Grade CA15, unless otherwise specified.

Ductile iron castings shall conform to ASTM A536, Grade 60-40-18, unless otherwise specified.

6.4.6.2—Malleable Castings

Malleable castings shall conform to ASTM A47/A47M, Grade 35018. The specified minimum yield strength shall not be less than 35.0 ksi.

6.4.6.3—Cast Iron

Cast iron castings shall conform to AASHTO M 105 (ASTM A48/A48M), Class 30.

6.4.7—Stainless Steel

Stainless steel may conform to one of the following:

- ASTM A240/A240M,
- ASTM A276/A276M, or
- ASTM A666.

Stainless steel not conforming to the above-listed specifications may be used, provided that it conforms to the chemical and mechanical requirements of one of the above-listed specifications or other published specifications that establish its properties and suitability and that it is subjected to analyses, tests, and other controls to the extent and in the manner prescribed by one of the listed specifications.

6.4.8—Cables**6.4.8.1—Bright Wire**

Bright wire shall conform to ASTM A510/A510M.

6.4.8.2—Galvanized Wire

Galvanized wire shall conform to ASTM A641/A641M.

6.4.8.3—Epoxy-Coated Wire

Epoxy-coated wire shall conform to ASTM A99.

6.4.8.4—Bridge Strand

Bridge strand shall conform to ASTM A586 or ASTM A603.

6.4.9—Dissimilar Metals

Where steel components, including those made of stainless steel, are in contact with aluminum alloy components in the presence of an electrolyte, the aluminum shall be kept from direct contact with the steel. The steel components may include structural members, structural fasteners, washers and/or nuts.

C6.4.9

Galvanic corrosion can occur when steel components, including those made of stainless steel, are coupled with aluminum in the presence of an electrolyte. The aluminum part acts as an anode and will be sacrificed in time. This galvanic corrosion can be prevented by isolating the two materials from each other. Materials such as dielectric elastomeric spacers have also been used to keep aluminum alloy parts from direct contact with steel or other dissimilar metals. Additional information can be found in AASHTO (2013, 2015) under the Aluminum Design Sections.

6.5—LIMIT STATES**6.5.1—General**

The structural behavior of components made of steel or steel in combination with other materials shall be investigated for each stage that may be critical during construction, handling, transportation, and erection as well as during the service life of the structure of which they are part.

Structural components shall be proportioned to satisfy the requirements at strength, extreme event, service, and fatigue limit states.

6.5.2—Service Limit State

The provisions of Article 2.5.2.6 shall apply as applicable.

Flexural members shall be investigated at the service limit state as specified in Articles 6.10 and 6.11.

C6.5.2

The intent of the service limit state provisions specified for flexural members in Articles 6.10 and 6.11 is primarily to prevent objectionable permanent deformations due to localized yielding that would impair rideability under expected severe traffic loadings.

6.5.3—Fatigue and Fracture Limit State

Components and details shall be investigated for fatigue as specified in Article 6.6.

The fatigue load combinations specified in Table 3.4.1-1 and the fatigue live load specified in Article 3.6.1.4 shall apply.

Flexural members shall be investigated at the fatigue and fracture limit state as specified in Articles 6.10 and 6.11.

Bolts subject to tensile fatigue shall satisfy the provisions of Article 6.13.2.10.3.

Fracture toughness requirements shall be in conformance with Article 6.6.2.1.

6.5.4—Strength Limit State

6.5.4.1—General

Strength and stability shall be considered using the applicable strength load combinations specified in Table 3.4.1-1.

A special load combination for investigating the constructibility of steel superstructure components for which the force effects due to loads applied to the fully erected steelwork are quantified shall be considered as specified in Article 3.4.2.1.

6.5.4.2—Resistance Factors

Resistance factors, ϕ , for the strength limit state shall be taken as follows:

- For flexure $\phi_f = 1.00$
- For shear $\phi_v = 1.00$
- For axial compression, steel only $\phi_c = 0.95$
- For axial compression and combined axial compression and flexure in composite CFSTs $\phi_c = 0.90$
- For axial compression, composite columns $\phi_c = 0.90$
- For tension, fracture in net section $\phi_u = 0.80$
- For tension, yielding in gross section $\phi_y = 0.95$
- For torsion $\phi_T = 1.00$
- For bearing on pins in reamed, drilled, or bored holes and on milled surfaces $\phi_b = 1.00$
- For bolts bearing on material $\phi_{bb} = 0.80$
- For shear connectors $\phi_{sc} = 1.00$
- For high-strength bolts in tension $\phi_t = 0.80$
- For ASTM A307 bolts in tension $\phi_t = 0.80$
- For ASTM F1554 anchor rods in tension $\phi_t = 0.80$
- For ASTM A307 bolts in shear $\phi_s = 0.75$
- For ASTM F1554 anchor rods in shear $\phi_s = 0.75$
- For high-strength bolts in shear $\phi_s = 0.80$
- For block shear $\phi_{bs} = 0.80$

C6.5.4.2

Base metal ϕ as appropriate for resistance under consideration. The resistance factors used for compression loading for composite CFST members are larger than the resistance factors used for reinforced concrete members because composite CFST members have more predictable strength values under compression than reinforced concrete members (Marson and Bruneau, 2004); (Roeder, Lehman, and Bishop, 2010).

The resistance factors for truss gusset plates were developed and calibrated to a target reliability index of 4.5 for the Strength I load combination at a dead-to-live ratio, DL/LL, of 6.0. More liberal ϕ factors could be justified at a DL/LL less than 6.0.

- For shear, rupture in connection element $\phi_{vu} = 0.80$
- For truss gusset plate compression $\phi_{cg} = 0.75$
- For truss gusset plate chord splices $\phi_{cs} = 0.65$
- For truss gusset plate shear yielding $\phi_{vy} = 0.80$
- For web crippling $\phi_w = 0.80$
- For stability bracing $\phi_{sb} = 0.80$
- For weld metal in complete penetration welds:
 - shear on effective area $\phi_{e1} = 0.85$
 - tension or compression normal to effective area—same as base metal
 - tension or compression parallel to axis of the weld—same as base metal
- For weld metal in partial penetration welds:
 - shear parallel to axis of weld $\phi_{e2} = 0.80$
 - tension or compression parallel to axis of weld—same as base metal
 - compression normal to the effective area—same as base metal
 - tension normal to the effective area $\phi_{e1} = 0.80$
- For weld metal in fillet welds:
 - shear in throat of weld metal $\phi_{e2} = 0.80$
- For resistance during pile driving $\phi_{da} = 1.00$
- For axial resistance of piles in compression and subject to damage due to severe driving conditions where use of a pile tip is necessary:
 - H-piles $\phi_c = 0.50$
 - pipe piles $\phi_c = 0.60$
- For axial resistance of piles in compression under good driving conditions where use of a pile tip is not necessary:
 - H-piles $\phi_c = 0.60$
 - pipe piles $\phi_c = 0.70$
- For combined axial and flexural resistance of undamaged piles:
 - axial resistance for H-piles $\phi_c = 0.70$
 - axial resistance for pipe piles $\phi_c = 0.80$
 - flexural resistance $\phi_f = 1.00$
- For shear connectors in tension $\phi_{st} = 0.75$

The basis for the resistance factors for driven steel piles is described in Article 6.15.2. Further limitations on usable resistance during driving are specified in Article 10.7.8.

Indicated values of ϕ_c and ϕ_f for combined axial and flexural resistance are for use in interaction equations in Article 6.9.2.2.

6.5.5—Extreme Event Limit State

All applicable extreme event load combinations in Table 3.4.1-1 shall be investigated.

All resistance factors for the extreme event limit state, except those specified for bolts and shear connectors, shall be taken to be 1.0.

All resistance factors for ASTM F1554 bolts used as anchor rods for the extreme event limit state shall be taken to be 1.0.

C6.5.5

During earthquake motion, there is the potential for full reversal of design load and inelastic deformations of members or connections, or both. Therefore, slip of bolted joints located within a seismic load path cannot and need not be prevented during a seismic event. A special inspection of joints and connections, particularly in nonredundant steel tension members (NSTMs),

Bolted slip-critical connections within a seismic load path shall be proportioned according to the requirements of Article 6.13.2.1.1. The connections shall also be proportioned to provide shear, bearing, and tensile resistance in accordance with Articles 6.13.2.7, 6.13.2.9, and 6.13.2.10, as applicable, at the extreme event limit state. Standard holes or short-slotted holes normal to the line of force shall be used in such connections.

should be performed as described in the AASHTO *Manual for Bridge Evaluation* after a seismic event.

To prevent excessive deformations of bolted joints due to slip between the connected plies under earthquake motions, only standard holes or short-slotted holes normal to the line of force are permitted in bolted joints located within a seismic load path. For such holes, the upper limit of $2.4dtF_u$ on the bearing resistance is intended to prevent elongations due to bearing deformations from exceeding approximately 0.25 in. It should be recognized, however, that the actual bearing load in a seismic event may be much larger than that anticipated in design and the actual deformation of the holes may be larger than this theoretical value. Nonetheless, the specified upper limit on the nominal bearing resistance should effectively minimize damage in moderate seismic events.

6.6—FATIGUE AND FRACTURE CONSIDERATIONS

6.6.1—Fatigue

6.6.1.1—General

Fatigue shall be categorized as load- or distortion-induced fatigue.

C6.6.1.1

In the AASHTO *Standard Specifications for Highway Bridges* (2002), the provisions explicitly relating to fatigue deal only with load-induced fatigue.

6.6.1.2—Load-Induced Fatigue

6.6.1.2.1—Application

The force effect considered for the fatigue design of a steel bridge detail shall be the live load stress range. For flexural members with shear connectors provided throughout their entire length, and with concrete deck reinforcement satisfying the provisions of Article 6.10.1.7, dead load and live load stresses and live load stress ranges for fatigue design at all sections in the member due to loads applied to the composite section may be computed assuming the concrete deck to be effective for both positive and negative flexure. The long-term composite section shall be used for the dead loads and the short-term composite section shall be used for the live loads.

C6.6.1.2.1

Concrete can provide significant resistance to tensile stress at service load levels. Recognizing this behavior will have a significantly beneficial effect on the computation of fatigue stress ranges in top flanges in regions of stress reversal and in regions of negative flexure. By utilizing shear connectors in these regions to ensure composite action in combination with the required one percent longitudinal reinforcement wherever the longitudinal tensile stress in the concrete deck exceeds the factored modulus of rupture of the concrete, crack length and width can be controlled so that full-depth cracks should not occur. When a crack does occur, the stress in the longitudinal reinforcement increases until the crack is arrested. Ultimately, the cracked concrete and the reinforcement reach equilibrium. Thus, the concrete deck may contain a small number of staggered cracks at any given section. Properly placed longitudinal reinforcement prevents coalescence of these cracks.

Residual stresses shall not be considered in investigating fatigue.

It has been shown that the level of total applied stress is insignificant for a welded steel detail. Residual stresses due to welding are implicitly included through the specification of stress range as the sole dominant stress parameter for fatigue design. This same concept of considering only stress range has been applied to rolled,

These provisions shall be applied only to details subjected to a net applied tensile stress. In regions where the unfactored permanent loads produce compression, fatigue shall be considered only if the compressive stress is less than the maximum live load tensile stress caused by the Fatigue I load combination specified in Table 3.4.1-1.

bolted, and riveted details where far different residual stress fields exist. The application to nonwelded details is conservative. A complete stress range cycle may include both a tensile and compressive component. Only the live load plus dynamic load allowance effects need be considered when computing a stress range cycle; permanent loads do not contribute to the stress range. Tensile stresses propagate fatigue cracks. Material subjected to a cyclical loading at or near an initial flaw will be subject to a fully effective stress cycle in tension, even in cases of stress reversal, because the superposition of the tensile residual stress elevates the entire cycle into the tensile stress region.

Fatigue design criteria need only be considered for components or details subject to effective stress cycles in tension and/or stress reversal. If a component or detail is subject to stress reversal, fatigue is to be considered no matter how small the tension component of the stress cycle is since a flaw in the tensile residual stress zone could still be propagated by the small tensile component of stress. The decision on whether or not a tensile stress could exist is based on the Fatigue I Load Combination because this is the largest stress range a detail is expected to experience often enough to propagate a crack. When the tensile component of the stress range cycle resulting from this load combination exceeds the compressive stress due to the unfactored permanent loads, there is a net tensile stress in the component or at the detail under consideration, and therefore, fatigue must be considered. If the tensile component of the stress range does not exceed the compressive stress due to the unfactored permanent loads there is no net tensile stress. In this case, the stress cycle is compression-compression and a fatigue crack will not propagate beyond a heat-affected zone.

6.6.1.2.2—Design Criteria

For load-induced fatigue considerations, each detail shall satisfy:

$$\gamma(\Delta f) \leq (\Delta F)_n \quad (6.6.1.2.2-1)$$

where:

- γ = load factor specified in Table 3.4.1-1 for the fatigue load combination. For the investigation of load-induced fatigue in orthotropic decks, the provisions of Article 3.4.4 shall also apply. For the investigation of load-induced fatigue in cross-frames or diaphragms, the provisions of Article 3.4.5 shall also apply.
- (Δf) = force effect, live load stress range due to the passage of the fatigue load as specified in Article 3.6.1.4 (ksi)
- $(\Delta F)_n$ = nominal fatigue resistance as specified in Article 6.6.1.2.5 (ksi)

C6.6.1.2.2

Eq. 6.6.1.2.2-1 may be developed by rewriting Eq. 1.3.2.1-1 in terms of fatigue load and resistance parameters:

$$\eta \gamma (\Delta f) \leq \phi (\Delta F)_n \quad (C6.6.1.2.2-1)$$

but for the fatigue limit state,

$$\begin{aligned} \eta &= 1.0 \\ \phi &= 1.0 \end{aligned}$$

Where force effects in cross-frames or diaphragms in I-girder bridges, or in intermediate external cross-frames or diaphragms in composite box-girder bridges, are computed from a refined analysis, as specified in Article 4.6.3, fatigue details on these members subjected to a net tensile force as specified in Article 6.6.1.2.1 shall be investigated for load-induced fatigue. To determine the range of force in the cross-frame or diaphragm member under consideration, the single fatigue truck shall be positioned as specified in Article 3.6.1.4.3a, but with the truck confined to a single transverse position during each passage of the truck along the bridge.

Where force effects in cross-frames or diaphragms in I-girder bridges are computed from a refined analysis, the effect of positioning the fatigue truck in two different transverse positions located directly over the adjacent connected girder usually creates the largest range of force in these bracing members. However, there is an extremely low probability of trucks being simultaneously located in these two critical relative transverse positions over millions of cycles. Also, field observations have not indicated a significant problem with the details on these members caused by load-induced fatigue. Therefore, it is recommended that the fatigue truck be positioned to determine the maximum range of force in the cross-frame or diaphragm member under consideration, as specified herein (Reichenbach et al., 2021). The resulting force effects in cross-frame members are computed based upon the predicted force range in the cross-frame member divided by the effective net area of the member defined in Table 6.6.1.2.3-1, Condition 2.5 or 7.2 as applicable, to determine the stress range. Calculated stress ranges in cross-frame or diaphragm members are to be factored as specified in Article 3.4.5.

For composite box-girder bridges, force ranges due to load-induced fatigue in intermediate internal diaphragms or cross-frames and in internal and external support diaphragms or cross-frames are typically small. Consequently, an explicit evaluation of load-induced fatigue of the details on these members using refined analysis is generally not warranted. Intermediate external diaphragms or cross-frames in these bridges, however, are subjected to more substantial load-induced fatigue force ranges that should be investigated with procedures similar to those outlined for I-girder systems.

6.6.1.2.3—Detail Categories

Components and details shall be designed to satisfy the requirements of their respective detail categories summarized in Table 6.6.1.2.3-1. Where bolt holes are depicted in Table 6.6.1.2.3-1, their fabrication shall conform to the provisions of Article 17.1 of the AASHTO *LRFD Steel Bridge Fabrication Specifications*. Where permitted for use, unless specific information is available to the contrary, bolt holes in cross-frame, diaphragm, and lateral bracing members and their connection plates shall be assumed for design to be punched full size.

Except as specified herein for components and details on NSTMs, where the projected 75-year single-lane average daily truck traffic ($ADTT_{SL}$) is less than or equal to the applicable value of the 75-year ($ADTT_{SL}$) Equivalent to Infinite Life specified in Table 6.6.1.2.3-1 for the detail category under consideration, the Fatigue II load combination specified in Table 3.4.1-1 may be used in combination with the nominal fatigue resistance

C6.6.1.2.3

Components and details susceptible to load-induced fatigue cracking have been grouped into eight categories, called detail categories, by fatigue resistance.

Experience indicates that in the design process the fatigue considerations for detail categories A through B' rarely, if ever, govern. Nevertheless, detail categories A through B' have been included in Table 6.6.1.2.3-1 for completeness. Investigation of components and details with a fatigue resistance based on detail categories A through B' may be appropriate in unusual design cases.

Table 6.6.1.2.3-1 illustrates many common details found in bridge construction and identifies potential crack initiation points for each detail. In Table 6.6.1.2.3-1, "Longitudinal" signifies that the direction of applied stress is parallel to the longitudinal axis of the detail. "Transverse" signifies that the direction of applied stress is perpendicular to the longitudinal axis of the detail.

for finite life specified in Article 6.6.1.2.5. Otherwise, the Fatigue I load combination shall be used in combination with the nominal fatigue resistance for infinite life specified in Article 6.6.1.2.5. The single-lane Average Daily Truck Traffic, $(ADTT)_{SL}$, shall be computed as specified in Article 3.6.1.4.2.

For details on primary members fully or partially in tension, that are classified as NSTMs or system redundant members (SRMs), the Fatigue I load combination specified in Table 3.4.1-1 shall be used in combination with the nominal fatigue resistance for infinite life specified in Article 6.6.1.2.5.

Orthotropic deck components and details shall be designed to satisfy the requirements of their respective detail categories summarized in Table 6.6.1.2.3-1 for the chosen design level shown in the table, and as specified in Article 9.8.3.4.

Where the design stress range calculated using the Fatigue I load combination is less than or equal to the constant-amplitude fatigue threshold, $(\Delta F)_{TH}$, specified in Table 6.6.1.2.3-1 for the detail category under consideration, the detail will theoretically provide infinite life. Except for Categories E and E', for higher traffic volumes, the fatigue design will most often be based on the infinite life check. Table 6.6.1.2.3-1 shows for each detail category the values of $(ADTT)_{SL}$ Equivalent to Infinite Life above which the infinite life check governs, assuming a 75-year design life and one stress range cycle per truck.

The values of the 75-year $(ADTT)_{SL}$ Equivalent to Infinite Life given in the sixth column of Table 6.6.1.2.3-1 were computed as follows:

$$75\text{-year}(ADTT)_{SL} = \frac{A}{\left[\frac{0.80(\Delta F)_{TH}}{1.75} \right]^m (365)(75)(n)} \quad (C6.6.1.2.3-1)$$

using the values for A , m , and $(\Delta F)_{TH}$ specified in Table 6.6.1.2.3-1, a fatigue design life of 75 years, and a number of stress range cycles per truck passage, n , equal to one. These values were rounded up to the nearest five trucks per day. That is, the indicated values were determined by equating infinite life and finite-life resistances with due regard to the difference in load factors used with the Fatigue I and Fatigue II load combinations. For other values of n , the 75-year $(ADTT)_{SL}$ values in Table 6.6.1.2.3-1 should be modified by dividing by the appropriate value of n taken from Table 6.6.1.2.5-1.

For other values of the fatigue design life, the 75-year $(ADTT)_{SL}$ values in Table 6.6.1.2.3-1 should be modified by multiplying the values by the ratio of 75 divided by the fatigue life sought in years.

The use of fatigue details classified as detail category C or better is encouraged on primary members fully or partially in tension, that are classified as NSTMs or SRMs. Fatigue design of internally redundant members (IRMs) is discussed in the AASHTO *Guide Specifications for Internal Redundancy of Mechanically-Fastened Built-Up Steel Members*.

A strict prohibition on the use of all fatigue details classified as detail category D, E, or E' is not recommended. Details on cross-frame or diaphragm members in beam and girder bridges often utilize bolted details that are classified as detail category D and/or welded details that are classified as detail category E'. Field observation has not indicated a problem with such details on these members caused by load-induced fatigue. For cases where explicit evaluation of cross-frame or diaphragm live-load force effects using refined analysis is not recommended or warranted, such as I-girder bridges that are within the suggested skew and connectivity index limits provided in Article C6.7.4.1,

load-induced fatigue of the details on these members need not be evaluated according to the procedures specified herein.

The procedures for load-induced fatigue are followed for orthotropic deck design. Although the local structural stress range for certain fatigue details can be caused by distortion of the deck plate, ribs, and floorbeams, research has demonstrated that load-induced fatigue analysis produces a reliable assessment of fatigue performance.

Considering the increased Fatigue I live load factor, γ_{LL} , for orthotropic deck details specified in Article 3.4.4 and the cycles per truck passage, n , for orthotropic deck plate connections subjected to wheel-load cycling, e.g., rib-to-deck welds, specified in Table 6.6.1.2.5-1, the 75-year $(ADTT)_{SL}$ Equivalent to Infinite Life calculated from Eq. C6.6.1.2.3-1 is 740 trucks per day for fatigue Category C orthotropic deck plate connection details and 3,700 trucks per day for all other fatigue Category C orthotropic deck details. Thus, finite life design may produce more economical designs for the detail under consideration on lower-volume roadways with 75-year $(ADTT)_{SL}$ values equal to or less than these values.

Table 6.6.1.2.3-1—Detail Categories for Load-Induced Fatigue

Description	Category	Constant A (ksi^m)	Fatigue Growth Constant, m	Threshold (ΔF_{TH}) ksi	75-year ($ADTT$) _{SL} Equivalent to Infinite Life (trucks per day)	Potential Crack Initiation Point	Illustrative Examples
Section 1—Plain Material away from Any Welding							
1.1 Base metal, except noncoated weathering steel, with rolled or cleaned surfaces, or base metal with thermal-cut edges with a surface roughness value of 1,000 $\mu\text{in.}$ or less, but without re-entrant corners.	A	250×10^8	3	24	690	Away from all welds or structural connections	
1.2 Noncoated weathering steel base metal with rolled or cleaned surfaces designed and detailed in accordance with FHWA (1989), or noncoated weathering steel base metal with thermal-cut edges with a surface roughness value of 1,000 $\mu\text{in.}$ or less, but without re-entrant corners.	B	120×10^8	3	16	1120	Away from all welds or structural connections	
1.3 Base metal of members with re-entrant corners at copes, cuts, block-outs or other geometrical discontinuities with a surface roughness value of 1,000 $\mu\text{in.}$ or less, except weld access holes.	C	44×10^8	3	10	1680	At any external edge	
1.4 Base metal of rolled cross-sections with weld access holes with a surface roughness value of 1,000 $\mu\text{in.}$ or less.	C	44×10^8	3	10	1680	In the base metal at the re-entrant corner of the weld access hole	
1.5 Base metal at the net section of open holes in members with a surface roughness value of 1,000 $\mu\text{in.}$ or less (Brown et al. 2007), except as specified in Condition 1.6. All stresses shall be computed on the net section. (Note: See Condition 2.1 for holes with pretensioned high-strength bolts installed in standard-size holes.)	D	22×10^8	3	7	2450	In the net section originating at the side of the hole

6.6.1.2.4—Detailing to Reduce Constraint

Welded structures shall be detailed to avoid conditions that create highly constrained joints and crack-like geometric discontinuities that are susceptible to constraint-induced fracture, as summarized in Tables 6.6.1.2.4-1 and 6.6.1.2.4-2. If a gap is specified between the weld toes at the joint under consideration, the gap shall not be less than 0.5 in.

C6.6.1.2.4

The objective of this Article is to provide recommended detailing guidelines for common joints to avoid details susceptible to brittle fracture.

The form of brittle fracture being addressed has been termed “constraint-induced fracture” (CIF) and can occur without any perceptible fatigue crack growth and, more importantly, without any warning. This type of failure was documented during the Hoan Bridge failure investigation by Wright et al. (2003) and Kaufmann et al. (2004). Criteria have been developed to identify bridges and details susceptible to this failure mode as discussed in Mahmoud et al. (2005).

Attached welded elements parallel to the primary stress are sometimes interrupted when intersecting a full-depth transverse welded element. In regions subject to a net tensile stress under Strength Load Combination I, these elements are less susceptible to fracture and fatigue if the attachment parallel to the primary stress is continuous and the transverse attachment is discontinuous as shown in Tables 6.6.1.2.4-1 and 6.6.1.2.4-2. If a gap is specified between the weld toes at the joint under consideration, the gap must not be less than the specified 0.5-in. minimum; larger gaps are acceptable. If a gap is not specified, since the continuous longitudinal stiffener or lateral connection plate is typically welded to the web before the discontinuous vertical stiffener, the cope or snipe in the vertical stiffener should be reduced so that it just clears the longitudinal weld. The welds may either be stopped short of free edges as shown in Tables 6.6.1.2.4-1 and 6.6.1.2.4-2 or wrapped for sealing as specified in Article 6.13.3.7. A longitudinal stiffener or lateral connection plate may be discontinuous at the intersection, but only if the intersection is subject to a net compressive stress under Strength Load Combination I and the longitudinal stiffener or lateral connection plate is attached to the continuous vertical web stiffeners as shown in Tables 6.6.1.2.4-1 and 6.6.1.2.4-2; such a detail is recommended at intersections with bearing stiffeners.

Three conditions are associated with susceptibility to CIF at welded details: 1) a high level of net tensile stress including consideration of residual stresses; 2) a high degree of constraint preventing local yielding; and 3) a notch-like or crack-like planar discontinuity approximately perpendicular to the primary flow of tensile stress producing a stress concentration and providing a fracture initiation point. Since it is not practical to quantify the magnitude and distribution of residual stresses, it should be assumed that the first condition is present in any detail subject to a net tensile stress or stress reversal due to the design loads when evaluating the susceptibility of a detail to CIF. The presence of all three conditions at a given welded detail indicates an elevated susceptibility to CIF. Note also that the presence of intersecting welds does not necessarily equate to an elevated susceptibility to CIF, particularly

when the detail features fewer than three intersecting welded steel elements; for example, the intersection of flange-to-web welds with welded flange or web shop splices. Coletti et al. (2021) review the fundamental principles of constraint-induced fracture, and present a simple, generalized procedure, with examples, for evaluating steel-bridge welded details for susceptibility to constraint-induced fracture. The generalized procedure and examples are also presented in Coletti (2023).

Table 6.6.1.2.4-1—Details to Avoid Conditions Susceptible to Constraint-Induced Fracture at the Intersection of Longitudinal Stiffeners and Vertical Stiffeners Welded to the Web

Description	Net Stress State at Location of Intersection (under Strength Load Combination I)	Illustrative Example
At locations where a longitudinal stiffener is on the opposite side of the web from a transverse intermediate stiffener or connection plate	Tension, Compression, or Reversal	
At locations where a longitudinal stiffener must intersect a transverse intermediate stiffener or a connection plate Note the longitudinal stiffener is continuous.	Tension, Compression, or Reversal

Table 6.6.1.2.4-2 (cont.)—Details to Avoid Conditions Susceptible to Constraint-Induced Fracture at the Intersection of Lateral Connection Plates and Vertical Stiffeners Welded to the Web

Description	Net Stress State at Location of Intersection (under Strength Load Combination I)	Illustrative Example (Lateral bracing members not shown for clarity)
See also the provisions of Article 6.6.1.3.2. Note the transverse intermediate stiffener or connection plate is discontinuous.		
At the intersection of a lateral connection plate with a bearing stiffener when it is not practical to attach the lateral connection plate to a flange. See also the provisions of Article 6.6.1.3.2. Note the bearing stiffener is continuous. The same detail may be used at the intersection of a lateral connection plate with a transverse intermediate stiffener or connection plate if the intersection is subject to net compression only.	Compression Only	 The diagram shows a 3D perspective view of a structural connection. A vertical plate, labeled 'WEB PLATE', is intersected by a horizontal plate, labeled 'DISCONTINUOUS FITTED LATERAL CONNECTION PLATE'. The horizontal plate is shown with a gap at the intersection. To the right of the intersection, a vertical plate is labeled 'CONTINUOUS BEARING STIFFENER'. Arrows indicate forces or moments. A label 'SEE NOTE 1' points to the gap area.
Note 1: If a gap is specified between the weld toes, the recommended minimum distance between the weld toes is 0.75 in., but shall not be less than 0.5 in. Larger gaps are also acceptable.		

C6.6.1.2.5

Except as specified below in Eq. 6.6.1.2.5-4 and as specified for components and details on NSTMs in Article 6.6.1.2.3, the nominal fatigue resistance shall be taken as:

- Where the projected 75-year single lane average daily truck traffic ($ADTT$)_{SL} is greater than the 75-year ($ADTT$)_{SL} Equivalent to Infinite Life specified in Table 6.6.1.2.3-1 for the detail category under consideration, the Fatigue I load combination shall

be used and the nominal fatigue resistance for infinite life shall be taken as:

$$(\Delta F)_n = (\Delta F)_{TH} \quad (6.6.1.2.5-1)$$

- Otherwise, the Fatigue II load combination may be used and the nominal fatigue resistance for finite life shall be taken as:

$$(\Delta F)_n = \left(\frac{A}{N} \right)^{\frac{1}{m}} \quad (6.6.1.2.5-2)$$

in which:

$$N = (365)(75)n(ADTT)_{SL} \quad (6.6.1.2.5-3)$$

where:

- A = detail category constant taken from Table 6.6.1.2.3-1 (ksi^m)
- m = fatigue growth constant taken from Table 6.6.1.2.3-1
- n = number of stress range cycles per truck passage taken from Table 6.6.1.2.5-1
- $(ADTT)_{SL}$ = single-lane ADTT, as specified in Article 3.6.1.4
- $(\Delta F)_{TH}$ = constant-amplitude fatigue threshold taken from Table 6.6.1.2.3-1 (ksi)

The requirement on higher-traffic-volume bridges that the maximum stress range experienced by a detail be less than or equal to the constant-amplitude fatigue threshold provides a theoretically infinite fatigue life. This requirement is reflected in Eq. 6.6.1.2.5-1. Values of n for longitudinal members are based on the calibration reported in Kulicki et al. (2015).

The fatigue resistance above the constant-amplitude fatigue threshold, in terms of cycles, is inversely proportional to the fatigue growth constant, m , of the stress range, e.g., if the stress range is reduced by a factor of 2, the fatigue life increases by a factor of 2^m . This is reflected in Eq. 6.6.1.2.5-2.

The fatigue design life has been considered to be 75 years in the overall development of these Specifications. If a fatigue design life other than 75 years is sought, a number other than 75 may be inserted in the equation for N .

Figure C6.6.1.2.5-1 is a graphical representation of the nominal fatigue resistance for Categories A through E'.

Figure C6.6.1.2.5-1—Stress Range Versus Number of Cycles ($m = 3$)

The nominal fatigue resistance for base metal and weld metal at details where loaded discontinuous plate elements are connected with a pair of fillet welds or partial joint penetration groove welds on opposite sides of the plate normal to the direction of primary stress, or where partial joint penetration groove welds are transversely loaded in tension, shall be taken as:

$$(\Delta F)_n = (\Delta F)_n^c \left(\frac{0.61 - 0.56 \left(\frac{2a}{t_p} \right) + 0.68 \left(\frac{w}{t_p} \right)}{t_p^{0.167}} \right) \leq (\Delta F)_n^c \quad (6.6.1.2.5-4)$$

where:

- $(\Delta F)_n^c$ = nominal fatigue resistance for detail category C, determined from Eqs. 6.6.1.2.5-1 or 6.6.1.2.5-2, as applicable (ksi)
- $2a$ = length of the nonwelded root face in the direction of the thickness of the loaded plate (in.) For fillet-welded connections, the quantity $(2a/t_p)$ shall be taken equal to 1.0.
- t_p = thickness of loaded plate (in.)
- w = leg size of the reinforcement or contour fillet, if any, in the direction of the thickness of the loaded discontinuous plate element (in.)

Table 6.6.1.2.5-1—Cycles per Truck Passage, n

Longitudinal Members	
Simple-Span Girders	1.0
Continuous Girders:	
1) near interior support	1.5
2) elsewhere	1.0
Cantilever Girders	5.0
Orthotropic Deck Plate Connections Subjected to Wheel-Load Cycling	5.0
Trusses	1.0
Transverse Members	
Cross-frames and diaphragms	1.0
Floorbeams	
Spacing > 20.0 ft	1.0
Floorbeams	
Spacing ≤ 20.0 ft	2.0

Eq. 6.6.1.2.5-4 accounts for the potential of a crack initiating from the weld root and includes the effects of weld penetration. Therefore, Eq. 6.6.1.2.5-4 is also applicable to partial joint penetration groove welds, as shown in Figure C6.6.1.2.5-2, where such welds are transversely loaded in tension.

Figure C6.6.1.2.5-2—Loaded Discontinuous Plate Element Connected by a Pair of Partial Joint Penetration Groove Welds

The effect of any weld penetration may be conservatively ignored in the calculation of $(\Delta F)_n$ from Eq. 6.6.1.2.5-4 by taking the quantity $(2a/t_p)$ equal to 1.0. The nominal fatigue resistance based on the crack initiating from the weld root in Eq. 6.6.1.2.5-4 is limited to the nominal fatigue resistance for detail category C, which assumes crack initiation from the weld toe. Eq. 6.6.1.2.5-4 was developed for values of $(2a/t_p)$ ranging from 0.30 to 1.1, and values of (w/t_p) ranging from 0.30 to 1.0. For values of $(2a/t_p)$ less than 0.3 and/or (w/t_p) greater than 1.0, the nominal fatigue resistance is equal to the resistance for detail category C. The development of Eq. 6.6.1.2.5-4 is discussed in Frank and Fisher (1979).

For the purpose of determining the stress-range cycles per truck passage for continuous spans, a distance equal to one-tenth the span on each side of an interior support should be considered to be near the support.

The number of stress-range cycles per passage is taken as 5.0 for cantilever girders because this type of bridge is susceptible to large vibrations, which cause additional cycles after the truck has left the bridge (Moses et al., 1987) (Schilling, 1990).

Orthotropic deck details that are connected to the deck plate (e.g., the rib-to-deck weld) are subjected to cycling from direct individual wheel loads. Thus, the passage of one design truck results in five fatigue load cycles as each axle produces one load cycle. The force effect, Δf , can be conservatively taken as the worst case from the five wheels or by application of Miner's Rule to determine the effective stress range from the group of wheels.

The number of stress-range cycles per truck passage is taken as 1.0 for cross-frames and diaphragms based on the stress range spectra monitoring of existing bridges and analytical evaluation (Reichenbach et al., 2021). Secondary stress cycles in cross-frames and diaphragms

6.6.1.3—Distortion-Induced Fatigue

Load paths that are sufficient to transmit all intended and unintended forces shall be provided by connecting all transverse members to appropriate components comprising the cross-section of the longitudinal member. The load paths shall be provided by attaching the various components through either welding or bolting.

To control web buckling and elastic flexing of the web, the provision of Article 6.10.5.3 shall be satisfied.

6.6.1.3.1—Transverse Connection Plates

Except as specified herein, connection plates shall be welded or bolted to both the compression and tension flanges of the cross-section where:

- connecting diaphragms or cross-frames are attached to transverse connection plates or to transverse stiffeners functioning as connection plates,
- internal or external diaphragms or cross-frames are attached to transverse connection plates or to transverse stiffeners functioning as connection plates, and
- floorbeams or stringers are attached to transverse connection plates or to transverse stiffeners functioning as connection plates.

In the absence of better information, the welded or bolted connection should be designed to resist a factored 20.0-kip lateral load for straight, nonskewed bridges.

Where intermediate connecting diaphragms are used:

- on rolled beams in straight bridges with composite reinforced decks whose supports are normal or skewed not more than 10 degrees from normal, and
- with the intermediate diaphragms placed in contiguous lines parallel to the supports,

less than full-depth end angles or connection plates may be bolted or welded to the beam web to connect the diaphragms. The end angles or plates shall be at least two-thirds the depth of the web. For bolted angles, a minimum gap of 3.0 in. shall be provided between the top and bottom bolt holes and each flange. Bolt spacing requirements specified in Article 6.13.2.6 shall be satisfied. For welded angles or plates, a minimum gap of

are generally small in magnitude and do not significantly contribute to the load-induced fatigue damage of the detail.

C6.6.1.3

When proper detailing practices are not followed, fatigue cracking has been found to occur due to strains not normally computed in the design process. This type of fatigue cracking is called distortion-induced fatigue. Distortion-induced fatigue often occurs in the web near a flange at a welded connection plate for a cross-frame where a rigid load path has not been provided to adequately transmit the force in the transverse member from the web to the flange.

These rigid load paths are required to preclude the development of significant secondary stresses that could induce fatigue crack growth in either the longitudinal or the transverse member (Fisher et al., 1990).

C6.6.1.3.1

These provisions apply to both diaphragms between longitudinal members and diaphragms internal to longitudinal members.

The factored 20.0-kip load represents a rule of thumb for straight, nonskewed bridges (Keating, 1990). For curved or skewed bridges, the diaphragm forces should be determined by analysis. It is noted that the stiffness of this connection is critical to help control relative displacement between the components. Hence, where possible, a welded connection is preferred as a bolted connection possessing sufficient stiffness may not be economical.

For box sections, webs are often joined to top flanges and cross-frame connection plates and transverse stiffeners are installed, and then these assemblies are attached to the common box flange. In order to weld the webs continuously to the box flange inside the box section, the details in this case should allow the welding head to clear the bottom of the connection plates and stiffeners. A similar detail may also be required for any intermediate transverse stiffeners that are to be attached to the box flange. Suggested details are shown in AASHTO/NSBA (2020). The Engineer is advised to consult with fabricators regarding the preferred approach for fabricating the box section and provide alternate details on the plans, if necessary.

3.0 in. shall be provided between the top and bottom of the end angle or plate welds and each flange; the heel and toe of the end angles or both sides of the connection plate, as applicable, shall be welded to the beam web. Welds shall not be placed along the top and bottom of the end angles or connection plates.

6.6.1.3.2—Lateral Connection Plates

If it is not practical to attach lateral connection plates to flanges, lateral connection plates on stiffened webs should be located a vertical distance not less than one-half the width of the flange above or below the flange. Lateral connection plates attached to unstiffened webs should be located at least 6.0 in., but not less than one-half the width of the flange, above or below the flange.

The ends of lateral bracing members on the lateral connection plate shall be kept a minimum of 4.0 in. from the web and any transverse stiffener.

Lateral connection plates shall be centered on transverse stiffeners, whether or not the plate is on the same side of the web as the stiffener. The detailing of welded lateral connection plates shall also satisfy the provisions of Article 6.6.1.2.4.

C6.6.1.3.2

The specified minimum distance from the flange is intended to reduce the concentration of out-of-plane distortion in the web between the lateral connection plate and the flange to a tolerable magnitude. It also provides adequate electrode access and moves the connection plate closer to the neutral axis of the girder to reduce the impact of the weld termination on fatigue strength.

This requirement reduces potential distortion-induced stresses in the gap between the web or stiffener and the lateral members on the lateral plate. These stresses may result from vibration of the lateral system. It also facilitates painting and field inspection.

The typical detail where the lateral connection plate is on the same side of the web as the transverse stiffener is illustrated in Table 6.6.1.2.4-2. With regard to the second detail shown in Table 6.6.1.2.4-2, when there is interference from a cross-frame or diaphragm attached to the bearing stiffener, or from a transverse floorbeam or internal plate diaphragm, two separate lateral connection plates may be used on each side of the bearing stiffener, floorbeam, or internal plate diaphragm. Each individual connection plate is to be welded to the bearing stiffener, floorbeam, or internal plate diaphragm as shown, with the welds either stopped short of any free edges as shown in Table 6.6.1.2.4-2 or wrapped for sealing as specified in Article 6.13.3.7. When more than one pair of bearing stiffeners is used, two separate lateral connection plates may again be used with each individual connection plate welded to the outer face of the outermost stiffeners. Should a single lateral connection plate be used in this case, it need not be fitted around each individual stiffener, and need only be welded to the outer face of the outermost stiffeners.

6.6.1.3.3—Orthotropic Decks

Detailing shall satisfy all requirements of Article 9.8.3.6.

C6.6.1.3.3

The purpose of this provision is to control distortion-induced fatigue of deck details subject to local secondary stresses due to out-of-plane bending.

6.6.2—Fracture

6.6.2.1—Member or Component Designations and Charpy V-Notch Testing Requirements

Member or component designations as primary or secondary shall be determined according to Table 6.6.2.1-1, unless otherwise designated on the contract plans.

C6.6.2.1

Designation of members or components as shown in Table 6.6.2.1-1 is essential because this information affects various aspects of fabrication such as material purchasing, welding, and inspection. Fillet and partial joint penetration groove welds on primary members and
